M.Sc. Experimental Surgery

EFFECTS OF HAEMODIALYSIS ON ENDOTOXIN AND HAEMORRHAGIC SHOCK

by

CHARLES T. B. MOYO, M.D.

Research Assistant in Experimental Surgery,
Demonstrator in Physiology, McGill University

A thesis submitted to the Faculty of Graduate Studies and Research in partial fulfilment of the requirements for a degree of Master of Science.

Department of Experimental Surgery,
McGill University
Montreal.

August, 1963.

ACKNOWLEDGEMENTS

I would like to express my thanks to Dr. Ronald R. Webster, Professor of Experimental Surgery, for generously making the necessary arrangements and for providing the necessary facilities towards the working of this problem of shock.

I am greatly indebted to my teacher and director of this research project, Dr. Lloyd D. MacLean, Surgeon-In-Chief of the Royal Victoria Hospital. It was through his untiring and helpful guidance that this project came to completion. Without the patient and critical contribution of Dr. L. D. MacLean, it would have been difficult to carry out this research project to its final stage.

My sincere appreciation is extended to the Baxter Laboratories of Canada Ltd. (Travenol Laboratories Inc.) for their tremendous generosity in donating forty new kidney coils towards this project. Since dialysis was the principal form of treatment employed in this study, without their help it could not have been completed.

I wish to express my thanks to Smith-Kline and French Laboratories for the generous gift of twenty-four vials of Dibenzyline.

Dr. John B. Dossetor, Director of Renal and Urological Research at the Royal Victoria Hospital gave several very constructive suggestions on the study and behaviour of electrolytes and chemistries during endotoxin and haemorrhagic shock.

Dr. Stacey Day initiated me into the scientific world of Surgical Experimentation. He was a constant guide and a helpful colleague throughout the whole year. He was also generous to bioassay histamine for me in one series of my investigations. Mrs. Stacey Day, together with her husband, pooled their efforts to see that the delicate method of determining histamine levels in the blood was meticulously carried out.

Dr. David Moors, Resident in Urology spent a whole month with me, showing me all the intricacies of dialysing a dog. It was through his untiring efforts that I managed to master the technique of Kolff's method of Haemodialysis.

Dr. Stanley Skoryna was kind enough to give positive suggestions whenever I was in doubt.

I am indebted to the kind assistance of Mrs. Livia Voyles and Miss Ute Tappert, of the Royal Victoria Hospital, for their instruction on blood chemistries, technique and handling of the equipment. They patiently determined the pH, pCO_2, HCO_3 and Lactic Acid, whenever I needed the study of these chemistries. In the same connection, I wish to thank Dr. Deidre Edwards, Miss Margaret Evans and Miss Daphne Lang, for their help in the determination of blood electrolytes and hematocrits.

Miss Margo Oeltzschner, Medical Artist in the Department of Anatomy and Histology of McGill University, has executed all the skilful diagrammatic sketches and drawings in this thesis. Mr. Anthony Graham, the Medical Photographer in the same department, has cooperated actively in some photographic assignments to supplement the textual descriptions. The same credit is extended to Mr. Pierre Morin,

who, as a photographer and technician, was of inestimable value in this project.

Miss Lilian Smallman, R.N., of the Royal Victoria Hospital and Head Nurse on 4 Medicine, was generous in supervising the gas sterilization of our equipment at a time we could not afford the luxury of a new coil. The same appreciation is extended to Miss Mary Warnock, Supervisor of the Royal Victoria Operating Room Theatre, who was generous in keeping us supplied with clean, sterile kidney coils and tubings.

It would have been difficult to complete this project without the technical assistance of Mr. Albert Nagy, Mr. Maurice Martin and Mr. Stanley Hardy.

It has been a most pleasurable experience to enjoy the happy association of other investigators at the Donner Laboratories during the academic year. The help and advice of my colleagues, Dr. Thyvalikakatj Paul, Dr. Jack White, Dr. John Gentile, Dr. Peter Prud'homme, Dr. David McLeod and Dr. Jack McCallum, will always be appreciated.

Miss Ann Thompson, R.N., and Miss Carolyn Greer, R.N., have typed, retyped and helped in the editing of the manuscript.

Charles T. B. Moyo, M.D.

CHAPTER 1

INTRODUCTION

Knowledge of the cause and management of shock have been subjects of intensive investigation and speculation since the history of medicine.

For many years, the treatment of hemorrhagic shock has been centered about the concept that the main defect in this syndrome is the blood loss and that ideal treatment is the replacement of this loss with adequate transfusions. Alongside with fluid replacement, vasopressors have been extensively used in the treatment of any form of hypotension, with the assumption that the fall in blood pressure is a valid measurement of the blood volume deficit.

In bacteremic shock, massive antibiotics and adrenocorticoids have been used extensively (MacLean, 1962) with some convincing results. In spite of the advent of antibiotics, the mortality rate of patients with coliform bacteremic shock is still over 65% (Adcock and Hakanson, 1960), (Spink, 1960). In some areas this percentage is even higher.

Our knowledge of the dynamics of shock is better than it was fifty years ago. There is recognition that the development of shock is a very complex phenomenon, not necessarily causally related to any one factor. Shock results from a multiplicity of influences, hormonal, renal, circulatory, biochemical, humoral and enzymatic.

With the growing acceptance of the view that catecholamines are

the major offenders in the refractory state of shock and in the irreversible phenomenon, many investigators (Lillihei, 1962), (Wilson, 1963), (Longerbeam, 1962), (Corday, 1960), are objecting to the indiscriminate use of vasopressors during haemorrhagic and endotoxin shock. Ganglionic blocking agents are receiving preference over sympathomimetics (Nickerson and Carter, 1959), (Hakstian, et al, 1961), (Thomas, 1958), (Gourzis, et al, 1961), (Baez, et al, 1952).

With so many conflicting opinions as to the best management of the shock syndrome, we decided to tackle the biochemical aspect of the problem.

Hence, our objectives were to correct the pH by dialysing lactic acid and other organic acids (pyruvic acid and phosphate), which play a part in the irreversible phenomenon. Since byproducts of bacteria can be dialysed into the rinsing solution, we believe that by ultrafiltration of these harmful substances, we may cure or prolong survival time in animals. Since histamine and catecholamines are incriminated in the irreversibility of shock, we thought that these substances could also be dialysable. Dialysis in itself helps to correct hypovolemia and by so doing we hoped to counteract peripheral vascular pooling and aggregation of cells that occurs during shock. (Wiggers, 1950), (Lars-Eric Gelin et al, 1961), (Cameron, 1962), (Shoemaker, 1962), (Nickerson, 1959), (Aust, 1957).

CHAPTER II

REVIEW OF LITERATURE

A. HISTORICAL PERCEPTIVES

There is no problem in the field of medicine which has elicited so much interest of physicians and surgeons throughout the ages as 'shock'. Celsus at the beginning of the Christian Era, in describing the effects of traumatic shock wrote:

> Now when the heart is penetrated, much blood issues, the pulse fades away, the colour is extremely pallid, cold and malodorous sweat bursts out as if the body had been wetted by dew; the extremities become cold and death quickly follows.

In 1497, Brunschweig (1933) commented on the collapse which followed severe gunshot wounds, but he attributed this condition to poisoning of the wound by gunpowder. Even Billroth (1859), one of the greatest surgeons of all time, believed that gunpowder poisoning was partly responsible for some of the symptoms of shock.

Puerperal sepsis in the large hospitals of Europe is vividly described in Devils, Drugs and Doctors (Haggard 1953). Books on colonization of the Orient give diagnostic descriptions of victims of cholera, dying of bacteremia and dehydration hypotension.

As we move through the centuries, we see that bleeders, barbers, surgeons and physicians all recognized this syndrome of haemorrhagic and endotoxin shock without calling it as such. This word 'shock' was first used in the English translation from the works of the French surgeon LeDran (1743), who during the same year wrote:

> The bullet thrown by gunpowder acquires such rapid force that the whole animal machine participates in shock and agitation.

Ambroise Pare (1582) pointed out this syndrome of shock which he called 'commotion' as he thought it was caused by 'falling from a high place on something solid and hard' or 'by blows causing contusions, such as those caused by a stone or a mass or a blow of a lance or an artillery blow or thunder falling near a person'. He referred to the pallor, cold sweat, indetectable pulse as 'Petite Morte'. The original of this text reads:

> D'avantage faut entendre qu'outre les susdites fractures, il se fait une autre disposition appelée Commotion. Ou ébranlement et concussion du cerveau, qui cause semblables accidents que les fractures du Crâne: laquelle Commotion se fair pour avoir tombé de haut en bas sur chose solide et dure, ou par coups orbes, comme de pierre, ou d'une masse, ou d'un coup de lance, ou l'air d'un coup D'Artillerie, ou du tonnerre tombant près de la personne, voire de la main, ou autres semblables.

Subsequently there sprung other workers in this field of shock in the 18th, 19th, and 20th Centuries, to mention only a few men like: (1) Bell (1812), (2) Abernathy (1804), (3) Hunter (1812), (4) Cannon (1917), (5) Harkins (1935), (6) Wiggers (1950). All these men have given tremendous contributions in the field of shock.

Abernathy (1804) in his 'surgical observations' described a patient admitted into St. Bartholomew's Hospital, with an 'aneurism of the femoral artery', for treatment of which he tied the external iliac artery. The description of this patient's ninth day post-operative condition is suggestive of bacteremic shock.

> His pulse beat...160 in a minute, his tongue was covered with a dark brown fur, he looked agitated, and purge took place, which was not restrained till the following night by a cordial and opiate mixture.

PHOTOGRAPH I

This woundman, a generation later than Brunschweigh, shows cannon balls impinging themselves, one upon the arm and the other upon the leg. This picture actually represents all the possible causes of shock as conceived by physicians and barbers of the 19th Century. A lance falling near the left foot of the 'man' is also seen. It is also noted that over the upper third of the thigh, an eruption is seen. This represents the "great pox", which was becoming an important cause of shock at the time. (Courtesy Bilroth "Historical Studies on Gun Shot Wounds", 1859.)

Herman Fischer (1870) corroborated with current opinion in Germany on the concepts of surgical shock as '...paralysirenden Einfluss einer plötzlicher und heftigen Nervenver Letzung auf die Herzthätigkeit'. Translated into English this reads: '(Shock) is caused by a sudden and violent injury of the nerves, with a paralysing influence on the action of the heart.'

B. MODERN CONCEPTS OF PATHOPHYSIOLOGY OF THE SHOCK SYNDROME

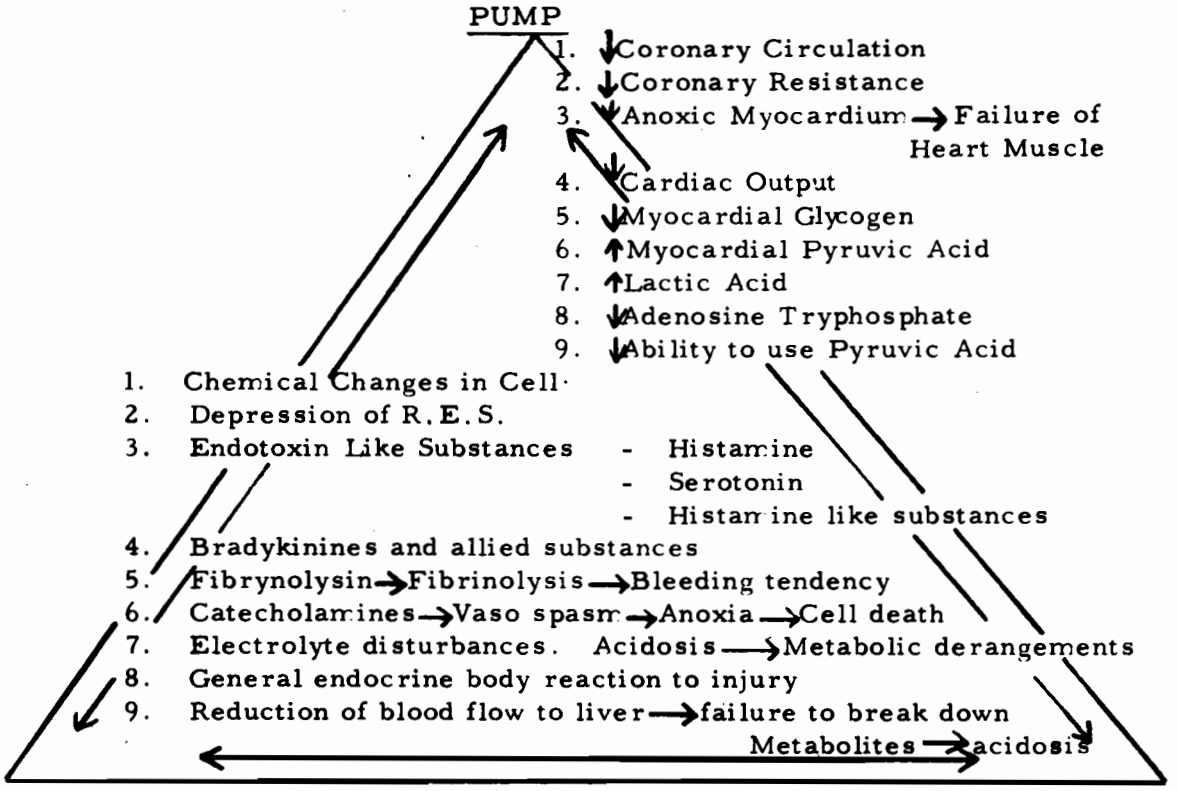
With the general progress over the last fifty years in the understanding of human biology, anatomy, physiology and biochemistry, the present concept of the pathophysiological mechanisms involved in the shock syndrome are clearer than they were during the time of Ambrose Pare (1582).

It is now more generally accepted by nearly all authorities on this subject that the factors which are principally concerned with shock or the target organs are: (1) the heart (Guyton, 1961, 1962) (Melcher, 1951). (2) the circulating volume (Fine, et al, 1955), (Blalock, 1930), (Phemister, 1927-28); (3) the peripheral vessels, arterioles, metarterioles, venules and capillaries (Wiggers, 1950), (Cameron, 1962), (Hardaway, 1959, 1961, 1962). In between these target organs, a host of physical, biochemical and metabolic changes occur, which lead to further depression of normal functions of the target organs, leading to irreversibility.

1. THE ROLE OF THE HEART

a) Failure of the Myocardium

The importance of the myocardium and its role in the development of the irreversible phenomenon in shock has been a subject of in-



CIRCULATING VOLUME

1. Reduced blood pressure
2. Reduced blood and/or plasma volume or not at all
3. Decreased venous return
4. Reduced oxygen supply to tissues
5. Circulating injurious substances from injured tissues (Burns or released by bacteria)

PERIPHERAL VESSELS

1. Regional peripheral resistance
2. Pooling and stasis in venules and capillaries of other organs
3. Decreased clotting time
4. Aggregation of cells → stasis → ↓ Tissues and cell perfusion → Cell death
5. Lecithinase → Possibility of endothelial disruption

DIAGRAM ILLUSTRATING BRIEF PATHOPHYSIOLOGY OF THE SHOCK SYNDROME

tensive investigation during the last decade. The shock state that accompanies severe myocardial infarction fortifies the theory that the failure of the pump mechanism is the primary cause of irreversibility. Increase in atrial pressure, diastolic ventricular and ventricular end diastolic pressure along with diminished ventricular stroke output (Crowell and Guyton, 1961, 1962), (Wiggers, 1942, 1947, 1950) give strong evidence of the importance of cardiac function in endotoxin and haemorrhagic shock. Izquieta and Pasternack (1946) observed depression of the ST segment during haemorrhagic and ischemic compression shock. Bloor (1958) and his associates observed the same abnormal electrocardiographic changes in haemorrhagic shock. Cardiac glycosides have been found to be beneficial in experimental traumatic shock (Keyl, 1956, 1957). This supports the important role of the myocardium in the production of irreversible haemorrhagic and endotoxin shock.

Kohlsteadht and Page (1944), Werle et al (1942) also support the theory that the primary failure of the myocardium is responsible for the irreversible phenomenon.

There are many different types of insults which can lead to myocardial deterioration in shock (Sarnoff, 1955). Nutritional deficiency, bacterial toxins, underlying heart disease (Guyton, 1961, 1962) may exert deleterious effects on the myocardium during shock. Many bacterial toxins, especially the endotoxins of the gram negative coliforms, have very toxic effects on the myocardium (Ross, 1957) .."Whatever the cause of a particular type of shock might be, death of a person finally ensues when the heart itself can no longer pump blood. In haemorrhagic shock, as well as many other types of shock, it is the heart itself that is the

primary and lethal deteriorating structure of the circulation and that deterioration which occurs in other parts of the circulation may vary well not be lethal at all." (Guyton, 1961)

According to the above theory, all other changes that accompany this phenomenon are secondary to myocardial failure.

On the other hand, (Weil et al, 1956), (Freedberg, 1944) (Zamecnik, 1947) and (Ebert, 1955a, 1955b) studying the venous pressures in dogs observed that the systemic venous pressure was either reduced or it remained the same during the experimental period. This indicates that congestive heart failure is not the cause of shock.

Sarnoff (1954), in his studies on haemorrhagic shock, observed that both the right and the left ventricles showed evidence of myocardial failure, dilitation of the heart and a decrease in the vigor and rapidity of arterial systole. Augmenting coronary flow, either mechanically or by administration of aramine, led to the decrease in right auricular pressure and dilatation of the heart. Melcher (1951) found, in dogs subjected to prolonged shock, areas of fatty infiltration and necrosis of cardiac muscle.

Hypovolemia and insufficient coronary blood flow leads to decrease in cardiac output, decrease in oxygen transport, oxygen availability and increase in oxygen debt and eventually to myocardial failure (Simeone et al, 1958a, 1958b), (Melcher and Walcott, 1951), (Weil, 1957), (Sarnoff, 1954), (Catchpole, 1955).

b) Decreased Coronary Circulation and Cardiac Output

Normally coronary blood flow as measured in the lower animals approximately constitutes four to five percent of the total cardiac

output. In human beings this would mean an average coronary flow of approximately 225 ml/minute (Guyton, 1962).

During haemorrhagic and endotoxin shock, there is a significant continuing decrease in coronary resistance with concommittant decrease in coronary circulation (Wiggers, 1950), (Eckenhoff et al, 1940, 1947), (Edwards, 1954), (Hackel and Goodale, 1955), (Opdyke, 1947), (Corday et al, 1960). This decrease in coronary flow leads to the generalized decrease in myocardial blood flow (Catchpole, 1955), (Churchill-Davidson et al, 1955). Decrease in coronary flow is accompanied by decrease in cardiac output and stroke volume (Osher, 1953), (Read et al, 1957), (Hackel and Goodale, 1955), (Hausner et al, 1940). Reduction in coronary flow has been associated with shock states regardless of cause and has been known to result in myocardial necrosis (Master et al, 1937), (Friedberg and Horn, 1939), (Melcher and Walcott, 1951). Normally about 65% of the oxygen in the arterial blood is removed before it circulates the coronaries. During shock, the oxygen saturation of arterial blood circulating the coronaries is greatly reduced. This leads to severe anoxia to the myocardium. Meneely (1946) postulated that prolonged anoxia of the myocardium can lead to increased permeability of the blood vessels in the heart, which would be an actual structural damage to the heart. Nobody has yet reduplicated Meneely's findings.

There is a progressive decline in cardiac output as shock reaches the terminal phase and a critical level of cardiac output, which, if lowered even slightly by withdrawal of blood, results in sudden death (Fine, 1947). There is temporary improvement in

cardiac output following transfusion (Wiggers, 1950).

c) Metabolic Effects of Shock on the Heart

Any prolonged hypotension leads to decreased oxygen consumption of the heart muscle. This is particularly prominent during the latter stage of shock. (Burdette, 1952). It has been shown that myocardial oxygen availability parallels closely the fall and rise in blood pressure seen in experimental haemorrhagic and endotoxin shock (Caliva, 1959). The prolonged anoxia causes many metabolic changes in the heart muscle. The myocardial extraction of lactate is increased during haemorrhagic shock (Edwards et al, 1954). Arterial concentration of pyruvate and lactate are increased during oligemic and normovolemic shock. Opdyke, (1947) also noticed reduction of myocardial extraction coefficient of pyruvate to negative values during shock, but sometimes there was increase in lactic acid (Burdette, 1950) and decreased adenosinetriphosphate (LePage, 1946).

Arterial glucose concentration is increased during olegemia, while myocardial glycogen drops. Myocardial pyruvate extraction is decreased while pyruvate in the coronary becomes higher than in the arterial blood.

None of these changes can be pointed out with certainty as the primary causes of the final state of irreversibility. There seems to be little doubt as to the synergistic effect of these pathophysiological mechanisms in precipitating irreversibility in shock.

2. EFFECT OF ENDOTOXIN AND HAEMORRHAGIC SHOCK ON PERIPHERAL VESSELS

a) Peripheral Resistance

"The animal had been bled to death, so that the vessels had an additional stimulus to produce contraction in them, as we know that all vessels in animals endeavour as much as possible to adapt themselves to the quantity of fluid circulating in them." (Hunter, J., 1812). Even as early as the beginning of the Nineteenth Century, prominent surgeons and physicians noticed the reaction of blood vessels to haemorrhagic shock. (Seelig and Lyon, 1909)

In haemorrhagic shock, the cardiovascular system tries to adjust itself in order to accommodate the smaller volume by increasing the peripheral resistance through generalized vasoconstriction. (Gessell, 1919), (Catchpole, 1955), (Erlanger, 1919), (Wiggers, 1950), (Cameron, 1962), (Lansing, 1962). This adjustment is brought about by vasomotor nerves situated in the walls of the capillaries. At the same time, increase in plasma catecholamines helps to maintain this vasomotor tone (Fine, 1962), (Vassant, et al, 1963), (Corday, 1960), (Wiggers, 1950), (Cameron, 1962). Catchpole (1955) noted that administration of l-nor-epinephrine during haemorrhagic shock did not lead to further peripheral vasoconstriction. However, there was a rise in blood pressure without increase in mean cardiac output. This is indicative of a differential increased resistance in different parts of the vascular beds. Wiggers (1950) observed the same phenomenon of differential vascular resistance. Vasodilation was noted to appear an hour before death (Fine, 1962).

Landgren and Neil (1951a, 1951b) demonstrated that stagnant hypoxia caused a heavy discharge of chemoreceptors and that this was correspondingly reduced by increasing systemic pressure. However, Field and Laverty (1958) do not subscribe to the theory of humoral vasoconstrictor material. Phemister and Hardy (1927, 1928) described vasodilator substances which develop in heparinized blood outside the body and therefore temporarily help tissue perfusion after reinfusion and thus increase cardiac output. The same authors believe that prolonged vasoconstriction that follows may be due to serotonin that is formed in the transfused blood or in the body of the animal during shock.

General vasoconstriction which occurs in all types of shock is aimed at redistribution of a large volume of blood to those structures whose function is vital for immediate survival. This vasoconstriction to other organs, if prolonged, may lead to the production of lethal factors or possibly to factors that lead to irreversibility (Cameron, 1962), (Alexander, 1955), (Adcock, 1960). Probably the haemorrhagic necrosis of the small bowel seen in fatal endotoxin and haemorrhagic shock may be due to intense vasoconstriction and oligemia of the gut (Lillehei, 1956, 1957), (Lillihei and MacLean, 1958). This may also be responsible for an increase in the hematocrit and Hemoglobin and a decrease in plasma volume (Lillihei and MacLean, 1958), (Fine et al, 1959).

The clinical situation of shock due to sepsis appears to be primarily related to the failure of peripheral vascular resistance. Gilbert et al, (1955) found in their patients that hypotension was not associated with decreased cardiac output, while peripheral resistance was reduced. These authors found that patients who received blood

contaminated with coliform bacilli or in septic abortion, exhibited these hemodynamic abnormalities. Hinshaw et al (1958) in animal experiments with Escherichia Coli endotoxin also noted a fall in peripheral resistance. Weil et al (1956) reported normal total peripheral resistance during the early phases of shock. This resistance, however, tended to decline as the animal progressed into shock (Hinshaw et al, 1958). This decline in peripheral resistance is probably due to the release of some parasympatholytic substance at the nerve endings. Vick and Hinshaw, (1960) believe this substance to be acetylcholine. There is a possibility also that this delayed vasodilatation in this type of shock may be due to accummulation of acid metabolites associated with a large oxygen debt (Hinshaw, 1958). On the other hand, Cannon and Bayliss (1919) claimed to have discovered a substance liberated from injured tissue, a histamine-like substance which on being absorbed circulated throughout the body, producing dilation and increased capillary permeability. Parsons and Phemister (1930) were unable to demonstrate any such vasodilation toxin coming by the blood stream from an injured area.

Zweifach et al (1956) noted that progressively increasing doses of endotoxin led to the decrease in the response of the terminal arterioles to epinephrine; at the same time the venules became more reactive. This physiological disturbance contributes to the stagnation of flow and peripheral pooling. Thomas (1956) and Zweifach (1956) claim that endotoxin intensifies the local vasoconstrictive action of epinephrine.

Species differences in reaction to endotoxin make this

subject more intriguing. Injection of endotoxin into a monkey leads to hypotensive changes which are not clearly understood (Ross, 1957) at the present stage in our knowledge of shock in primates. In the cat, venous pooling is noted primarily in the pulmonary vascular system and not in the splanchnic bed (Gilbert, 1960), while in the rat, marked liver congestion with haemorrhage suggests trapping of the blood in the splanchnic area. There is a similarity between the endotoxin vasomotor and vascular collapse with anaphylaxis. Probably this similarity is due to a common factor which depresses the reticuloendothelial system (Fine, 1959), (Frank, 1955), (Thomas, 1958). Studying the hemodynamics of patients with bacteremic shock, Vassant et al (1963) found that reduction in mean arterial pressure was accompanied by reduced cardiac output and increased peripheral resistance. This would indicate that the reduction in arterial pressure is due to a decline in cardiac output rather than due to arteriolar dilatation or so called 'vasomotor collapse'. Mean circulation time was prolonged, reflecting decreased velocity of blood flow. In gram negative shock patients, hypotension is associated with a marked reduction in cardiac output; vasodilation does not account for the hypotension (Vassant et al, 1963), (Wiggers, 1947, 1948). Deficit in venous return and venous pooling with decreased venous return account for the initial reduction in cardiac output (Weil, 1961), (Wiggers 1950), (Wiggers and Werle, 1942) and for the primary causes of bacteremic shock (Vassant et al, 1963).

b) <u>Venomotor Failure</u>

Venomotor failure also throws new light on the process of

blood pooling in shock. This is accounted as the primary cause in the reduction of venous return in haemorrhagic shock (Wiggers, 1950), (Alexander, 1955), (Zweifach, 1944), (Gelin et al, 1961). It seems that oscillatory behaviour of the vasomotor centres following haemorrhage (Guyton and Harnis, 1951) produces oscillations in venomotor tone as well as fluctuations in arteriolar tone (Green et al, 1943). The magnitude of venoconstriction evoked by haemorrhage indicates that this is a contributing factor in compensatory adjustments of the circulatory system. Venomotor tone tends to dissipate most markedly in critical hypotension (30 mm Hg). This is followed by muscular venules (Zweifach, 1944). It seems that venomotor failure heralds the period of irreversibility. Since there is little arteriolar dilatation (Alexander, 1955), (Wiggers, 1950) in endotoxin shock, this places upon the venomotor system a major responsibility for the hemodynamic failure of the circulation in shock. Alexander (1944) demonstrated that venomotor tone sharply rose with haemorrhage just as in arterioles, but it is not maintained with prolongation of hypotension. Failure of the venomotor mechanisms is an important factor in shock, as it leads to pooling and aggregation of blood in the venous system (Gelin et al, 1961), (Hardaway, 1961a, 1961b, 1962). This in turn leads to decreased cardiac output, decreased nutrient flow, anoxia, metabolic changes and then finally to the irreversible state of shock.

It is concluded that failure of the venomotor mechanisms is an important factor in shock.

c) Coagulation Mechanisms in Shock

Hewson (1846) noted that in bleeding human patients "the blood which issued last coagulated first". Turpini and Stefanini (1959) confirmed Hewson's findings, and in addition they found that during haemorrhagic and traumatic shock, hypercoagulability was followed by hypocoagulability, with a fall in clotting elements and an increase in fibrinolysin activation.

Endotoxin (Hardaway et al, 1959, 1961a, 1961b) and haemorrhagic shock have been shown to be associated with abnormalities in the coagulation mechanism (Hardaway and McKay, 1959, 1962a, 1962b) (Gans, 1960). Intravascular clotting and hypercoagulability of the blood has been a constant finding in all types of shock (Crowell and Read, 1955a, 1955b), (Crowell, 1960). However, it seems to be encountered to a greater degree in haemorrhagic than in endotoxin shock.

The author observed, while taking blood samples for chemistries and electrolytes, that when a dog had been in shock for 3½ hours, the blood was so hypercoaguable that more heparin had to be added in order to keep the blood in a liquid state. MacKay (1955, 1956) and his associates noted the same changes in coagulation of the blood after administration of incompatible blood transfusion.

The cause of decreased clotting during haemorrhage is obscure. Norepinephrine is known to cause significant drop in clotting time of dogs (Hardaway, 1962). Decrease may be again a protective mechanism aimed at staunching haemorrhage (Hardaway, 1962). In severe haemorrhage, the blood is so hypercoagulable that intravascular

coagulation takes place (Ehrlick, 1963). This results in the body's depletion of fibrinogen and prothrombin (Tagnon et al, 1946). With microcirculation reduced to these dangerous levels, perfusion to vital organs is markedly reduced and thus tissue death takes place especially in those areas which have a great need for continuous blood supply such as the kidney and the gastrointestinal mucosa. Irreversibility was correlated with a fall in prothrombin and fibrinogen which denoted intravascular coagulation and aggregation of cells (Hardaway, 196la, 1961b, 1962). Injection of thrombin produced the same intravascular phenomenon (Hardaway, 1960). It seems that death occurs due to tissue necrosis as a result of thrombi. The focal necrosis and haemorrhages that occur in the liver, kidneys, pancreas and sometimes in the heart following irreversible haemorrhagic and endotoxin shock are due to these vascular disturbances (Hardaway, 1959).

Hypercoagulability and survival are correlated, since hypocoagulability heralds the appearance of irreversibility (Hardaway et al, 1963). Probably autogenous heparin appears later and causes the hypocoagulability. Neutralization of this heparin-like substance by protamine seems to point to the fact that the substance is heparin, which is probably released by the liver (Hardaway et al, 1963). The same authors claim protection of the animal against lethal influences of haemorrhagic shock by administration of fibrinolysin, probably by dissolution of established clots in visceral capillaries and destruction of fibrinogen.

In splenectomized animals (Hardaway, 1962) the fibrinogen

levels were not only lower initially, but fell less. This was much more significant in permanent survivors. These findings suggest that there is less total fibrinogen converted into fibrin in splenectomized than in normal dogs. Splenectomy does seem to give some protection against irreversible haemorrhagic shock.

Besides the aggregation and sequestration of blood in the capillaries and venules, there are some enzymatic derangements which seem to take place as a result of prolonged tissue and cellular anoxia. Lecithinase is liberated in the anoxic areas of the circulation (Hardaway, 1963). This enzyme hydrolyses the cement of the endothelium, leading to more plasma loss into the extravascular spaces. This may be one of the causes of focal necrosis found in some organs following protracted endotoxin hypotension.

Whatever the actual pathological derangements are in peripheral vessels, there is no doubt that this part of the circulation has a role to play in the irreversible phenomenon of shock.

3. CIRCULATING VOLUME IN HAEMORRHAGIC AND ENDOTOXIN SHOCK

a) Vasovagal Syncope

Reduction in effective blood volume and venous return are important in the development of circulatory failure. Circulatory failure can occur without any external loss of blood, characterized by fall in right atrial pressure and slight increase in heart rate. Unpleasant smells, pain, psychic fright or physical trauma without any loss of blood, either internally or externally, may result in fainting. This form of shock is called vasovagal syndrome (Lewis,

1932). In this syndrome, peripheral resistance is markedly decreased, suggesting a reflex vasodilation as the dominant factor (Warren et al, 1945).

There is increase of flow through the muscles while that of the skin and the brain is decreased. Muscular blood flow is reduced by sympathetic nerve block. Sudden syncope which is followed by reduction of arterial pressure is due to reflex vagal slowing and/or dilatation of the blood vessels dominantly in the muscles.

b) Volume Changes During Haemorrhagic Shock

This type of shock results initially from reduction in blood volume. It was Keith (1919) who first demonstrated decreased volume of the circulating blood in shock. Although haemorrhage may be the inciting cause of this syndrome, the signs and symptoms, as well as the ensuing physiological and biochemical alterations, are not entirely the direct effect of the blood volume deficit per se. Some factors must enter the picture to produce these changes.

Between the initiating blood volume loss and the final end result, there are many compensatory reactions, many of which have a bearing on irreversibility. A chain of events occurs after haemorrhage and they are so linked together that a vicious cycle occurs. Haemorrhage and hypovolemia stimulate the activity of the sympathetic nervous system, which leads to increased production of epinephrine (Walker, et al, 1959), (Cameron, 1962), (Wiggers, 1950), (Harkins, 1935), Longerbeam, 1962), (Longerbeam et al, 1962), (Corday, 1960), (Shoemaker, et al, 1961), (Walton, et al, 1959).

This compensatory response leads to initial increase of

blood flow through the liver, increased portal vein pressure and increased resistance to flow across the liver, (Shoemaker, 1961) which gradually decreases due to regional resistance (Shoemaker, et al, 1961). This resistance in hepatic flow leads to increased portal vein pressure which in turn hinders blood flow from the splanchnic area. With generalized impairment in the circulation, there is impairment of the metabolic and biochemical functions of the liver. The interference with hepatic circulation eventually leads to aggregation of cells in hepatic sinusoids and small peripheral vessels and the same vicious cycle described before comes into play again, eventually leading to irreversibility.

Replacement of the blood volume deficit after protracted and severe haemorrhagic shock does not avert the phenomenon of irreversibility. Therefore decrease in blood volume which is postulated to be a sequellae of capillary permeability and/or blood loss does not appear to be the main factor in irreversibility.

c) Blood Volume Changes in Endotoxin Shock

It is generally believed that there is a reduction in the volume of circulating blood in all types of shock. In shock without haemorrhage, the diminuation of blood volume is attributed to passage of fluid from the blood into the tissues possibly as a result of some toxic substance (Blalock, 1930a, 1930b), which disrupts the peripheral vessels. Lillihei and MacLean (1958), on studies of blood volume in ninety dogs, reported an increasing plasma loss reaching an average of 35% immediately prior to death. Lillihei (1962)

working separately, also reported a similar plasma loss in irreversible haemorrhagic shock.

Penner and Bernheim (1942) working with shiga toxin noticed that after injection of the toxin into the dog, there was a rise in hemoglobin, red cell count, hematocrit reading and specific gravity of whole blood. The values of these parameters indicate a decrease in circulating blood volume.

Crenshaw, et al (1962), using S^{35} labelled sodium sulphate I^{131} and Cr^{51}, concluded that during acute haemorrhagic shock in dogs, there is a marked diminution in functional extracellular fluid volume. This is attributed to the defect in internal distribution of the extracellular fluid. In their experiments, the total functional extracellular fluid loss averaged 31%. These results were obtained from patients who had been admitted during acute haemorrhagic shock.

The average blood volume deficit in endotoxin and in haemorrhagic shock after transfusion in rabbits and dogs is 7.0% (Grable et al, 1963). In fact this team claims to have found no change or an increase in plasma volume before death.

It is possible that during haemorrhagic and endotoxin shock, substances such as histamine, proteases, kinins, polypeptides and other permeability factors are responsible for capillary permeability in shock - thus allowing the loss of circulating plasma volume (Miles, 1961), (Stetson, 1961). However, replacement of the same amount of fluid loss did not increase the survival rate. (Grable et al, 1963), (Lillehei, 1962).

On the other hand there are others who claim that plasma volume during endotoxin shock remains within normal range (Ebert and Astead, 1941). Gilbert (1960) found that during the early stages of uncomplicated endotoxin shock, there was no critical reduction in total blood volume. However, this reduction seems to be a contributory factor during the later stages of shock.

Intravenous injection of typhoid vaccine, produced no change in hematocrit of plasma volume as measured by T-1824 (Favorite and Morgan, 1942), (Gibson and Kopp, 1938). Altschule et al (1945) reported an increase in plasma volume in febrile conditions. Patients dying with shock from peritonitis or from a transfusion contaminated by gram-negative organisms were found to have normal blood volume and hematocrit (Emerson and Ebert, 1945), (Richards, 1943-44), (Stevens et al, 1953).

The correlation between plasma volume and irreversibility is still obscure. Death occured in dogs whose plasma volume deficit had been corrected (Lillihei and MacLean, 1958), and it has been shown in experimental peritonitis that plasma volume fall does not determine death or survival (Ebert, 1949), (Frank et al, 1955).

There are reasons to suspect that a fall in plasma volume must eventually occur. Histological evidence of edema in the intestine (Penner and Bernheim, 1942) seems to substantiate this loss. Studies with tagged I^{131} showed the highest concentration of this isotope in the intestine (Aust and Johnson, 1957, 1958), (Aust, 1959).

The later fall in plasma volume is probably due to increase in capillary permeability which has been pointed out previously.

There are experimental data which indicate that plasma volume falls during endotoxin shock. There is progressive rise in hematocrit as the dog sinks deeper into shock (Penner and Bernheim, 1942). Hematocrit increases closely parallel plasma losses (Lillehei and MacLean, 1958). Blood diarrhoea often starts one to three hours after endotoxin administration and continues until death. The author's own observations confirmed these findings.

Blood determinations made in patients with bacteremic shock following contaminated blood (Stevens et al, 1953) were within normal limits. Ebert and Stead (1941) investigating the hemodynamics of circulatory failure in acute infections did not find any significant blood volume reductions. Muelheims (1959) and his co-workers have demonstrated that after severe haemorrhage, the liver shows a decrease in red blood cell volume of about 50%.

Falling plasma volume reported in dogs is probably the result of dehydration or loss of fluid into the interstitial space or both. Braude et al (1955), working on rabbits and using endotoxin tagged with radio active sodium chromate, demonstrated that the distribution of radioactivity was greatest in the plasma for two hours, after which its highest concentration was found in the liver and the buffy coat (Braude, 1955a, 1955b).

Differences in figures on plasma volume changes in endotoxin shock may be due to differences in the techniques of estimating plasma loss. This problem of volume changes could be re-evaluated by using more than one species and standardizing the method of

measuring plasma volume using modern instruments such as the volemetron.

4. THE ROLE OF THE LIVER DURING SHOCK

a) Circulatory Changes

Two-thirds of the hepatic flow is from the portal vein and one-third is from the hepatic artery (Bard, 1956). Decrease of systemic blood pressure is followed by a decrease in both portal and hepatic artery circulation.

The liver plays a very important role during haemorrhagic and endotoxin shock. The hemodynamic events that follow haemorrhage or bacteremia are reflections of more dire consequences in the splanchnic vasculature than in any other system of the body. The increased hepatic vascular resistance to blood flow produces in effect, a physiologic dam (Hamrick, 1955), (Shoemaker, 1962), (Kuida et al, 1958). With increasing haemorrhage, the portal vein flow decreased almost linearly (Wiggers, 1946), (Shoemaker, 1961). The pooling of blood in the splanchnic area is probably due to the constriction of hepatic veins. Adminstration of E. Coli endotoxin is followed by an immediate decrease in blood pressure. This initial phase of hypotension is due to decreased venous return, caused by initial hepatic venous spasm followed by sequestration of blood and plasma in the intestine and a consequent decrease in cardiac output (Aust and Johnson, 1958), (MacLean, et al, 1956), (MacLean and Weil, 1956). Farber (1954) and his associates have shown that mechanical obstruction of hepatic veins causes hypotension and decreased venous return to the heart. This increase in portal vein pressure and intestinal

congestion encountered in haemorrhagic and endotoxin shock has been questioned by many investigators (Lillehei, 1956, 1957), (Lillehei and MacLean, 1958), (Schweiburg et al, 1957), (Frank et al, 1946), (Cohn and Parsons, 1950), (Johnson, 1958), (Zanetti, 1952). This constriction of hepatic veins resembles histamine shock (Hinshaw, 1960, 1961 and 1962), (Wiggers, 1950).

Previous measurements of the portal vein flow in acute shock recorded a decrease in flow but did not indicate a significant increase in mesenteric vascular resistance (Cull, et al, 1956), (Selkirk and Brecher, 1956), (Levy, 1958).

As the hepatic resistance increases and falling hepatic blood flow progresses, a critical situation arises where the diameter of the sinusoids produces alterations in the blood velocity. Exaggerated Rouleau formation occurs and leads to sludging or aggregation of red cells in the hepatic sinusoids (Gelin, 1956, 1961), (Gelin and Shoemaker, 1961), (Knisely et al, 1945). Congestion and hyperemia of the hepatic sinusoids take place in the pericentral area. Sludging of cells in hepatic sinuscids was also seen in burns (Gelin, 1956) and in haemorrhagic shock (Knisely, 1946), (Wiggers, 1950). However, Hamrich and Meyers (1955) believe that although there is sludging, there is no alteration in the oxygen consumption in the splanchnic area. It is this sequestration of blood in this area that gives rise to reduction in effective circulating volume (Shoemaker, 1962). Histological evidence of acute hyperemia and congestion of the liver have been observed both in man and experimental animals dying of shock.

b) Biochemical Derangements

As shock progresses from impending to the irreversible state, there is a depletion of glycogen stores. This is reflected by the hyperglycemia which is markedly prominent during the hypotensive period of shock (Beatty, 1945). It was Claude Bernard who was the first man to show that haemorrhage produces hyperglycemia. The glycogen release is activated by the sympathetic nervous system (Engel, 1952), (Wiggers, 1950), which also stimulates the adrenal medulla to liberate adrenaline and finally the activation of the liver to liberate glucose. Engel (1943) attributed the hyperglycemia to increased glucogenolysis. Wiggers (1950) is of the opinion that elevated levels of glucose are due to the failure of the liver to synthesize glycogen from glucose and lactic acid and that there is also a concomittant depression of the tissue's ability to utilize glucose efficiently. The liver's uptake of oxygen is decreased and its ability to deaminize amino acids and synthesize urea from dl-alanine and ammonium lactate is impaired (Wilhelmi, 1945), (Wiggers, 1950). The energy reserves represented by stores of A.T.P. and A.D.P. are diminished (Wiggers, 1950), (Levenson, 1961), (McShan et al, 1945), (Lepage, 1946). There is intracellular accumulation of creatinine, inorganic phosphates and other nitrogenous metabilites (Cowley et al, 1960), (Nelson and Seligson, 1953), (Fishman and Levine, 1948).

Due to the depression of the liver circulation, there is a loss of liver potassium and an increase in liver sodium chloride.

Prolonged haemorrhage leads to increase of liver potassium by 50% and decrease of liver sodium by 50%. Thus liver electrolyte derangement and the additional enzymatic disturbances lead to the accumulation of water in the liver (Darrow and Engel, 1945).

The biochemical changes in the liver, the depletion and the reduction of oxygen saturation in the portal system play an important role in the irreversible phenomenon (Lepage, 1946), (Frank et al, 1946), (Seligman et al, 1947). There is a reduction in the secretion of bile during shock. Bromsulpthalein clearance is diminished (Fine, 1947), (Wiggers, 1950), (Levenson et al, 1961). The congestion and discoloured state of the liver observed during haemorrhagic and endotoxin shock, especially in the latter, suggest that the liver must play some important role during the period of stress. The friable congested liver found at death from haemorrhagic shock suggests severe reduction of liver function during haemorrhagic shock.

c) Toxic Factors

Seligman et al (1947) found that by viviperfusion of the liver for five to nine hours with arterial blood from the donor, 88% of the dogs in haemorrhagic shock, irreversible to transfusion, recovered, while dogs which were perfused through the femoral artery had a 77% mortality rate. In the same year, Fine and Seligman (1947), working on dogs in which therapeutic transfusions had failed, obtained results similar to Seligman's group.

Frank et al (1946) prevented or delayed the onset of irreversible shock by increasing arterial blood flow to the liver.

Elliott (1951) reported higher survival rate on dogs which had received intravenous injections of sodium dehydrocholate. At the same time he noticed that by increasing arterial blood flow to the liver, he increased the survival rate of dogs subjected to haemorrhagic shock.

Chambers et al (1944) suggested the presence of a circulating toxin in haemorrhagic and torniquet shock. Certain toxins cause hepatic vein contraction in dogs and this results in arterial hypotension, hepatic congestion and increased portal vein pressure (Thomas and Essex, 1949). Shorr (1945) and his associates are of the opinion that shock is due to an endogenous vasopressor toxin, which is principally found in the liver. However, if a toxin is responsible for the lethal outcome of shock, it would be difficult to account for the healthy state of the donor dog, while the recipient dies in shock. There must be some neutralizing element in the donor dog which is not available in the recipient in spite of the free intermixture of the two blood streams (Fine, 1947). Shorr (1945) found that the toxin is elaborated by anoxic liver even in vitro and it is inactivated by healthy liver tissue. The same investigator and his team isolated reduced ferritin from shocked liver and claimed this material as the toxin responsible for irreversibility (Shorr et al, 1957).

These findings seem to indicate that the liver manufactures a toxin which is capable of paralysing the vascular tone. There may be a hepatic hormone which normally maintains vascular tone, which like hypertensinogen and fibrinogen, disappears as the hepatic cells become increasingly incompetent (Fine, 1952). On the other

hand, Prinzemetal (1944) claims that there is a principle in certain liver extracts which possesses power of decreasing mortality and increasing survival time in animals subjected to burn shock.

The important role of the liver during endotoxin shock is demonstrated by Seligman (1948) who injected radioactive (I^{131}) Serratia marcescens into rats. He found that the greatest radioactivity was in the liver.

5. THE ROLE OF THE INTESTINE IN IRREVERSIBLE HAEMORRHAGIC AND ENDOTOXIN SHOCK

There is considerable overlap in the mesenteric and hepatic changes that take place during shock. The anatomical and circulatory relationships of these two systems are well known.

The role of the intestine in irreversible haemorrhagic and endotoxin shock has been widely studied by many investigators (Blalock and Levey, 1937), (Blattberg et al, 1960), (Braude, 1955a, 1955b), (Lillehei, 1957, 1958, 1962). Preservation of blood flow to the gastrointestinal tract by cross circulation (Lillehei, 1957) has resulted in protection of 80% of dogs from going into irreversible shock. Blood diarrhea, edema, mucosal haemorrhages and necrosis of the small bowel, which are a sine qua non of the irreversible shock syndrome, were prevented by this form of treatment. It appears that the site of irreversibility is the gastrointestinal tract (Henly, 1958). The reduction of normal portal flow from the average of 31.6cc./min./kg. to 18.5cc./min./kg. (Henly et al, 1958), (Corday, 1960) during the hypotensive period may be responsible for the haemorrhagic necrosis of the bowel.

After administration of endotoxin, the liver weight rises

abruptly while the intestinal weight rises over a period of 4-6 hours until death ensues. (Aust and Johnson, 1958). The increase in the weight of these organs is probably due to plasma sequestration in the intestines (Hinshaw et al, 1958a, 1958b). MacLean (1956) and his associates have demonstrated a marked loss of fluid into the intestine following endotoxin shock with small bowel weight rising to as much as 196-770 grams in the hour following endotoxin injection. The fluid loss partly accounts for the hypotension observed. Aust and Johnson (1958) believe that endotoxin causes capillary permeability to the degree where leakages of large protein molecules in the intestinal spaces occur. This explains the edematous congested intestine that is found at autopsy of dogs dying of irreversible endotoxin and haemorrhagic shock (MacRay, 1958). The pathophysiological intestinal similarities between endotoxin, haemorrhagic and traumatic shock have led to the belief that all forms of shock have a bacterial or endotoxin etiology for the production of irreversibility (Fine, 1952, 1954, 1958), (Fine et al, 1959), (Jacob et al, 1954), (Schweinburg et al, 1954), (Lillehei, 1957), (Lillehei and MacLean, 1958).

On the basis of this hypothesis, Lillehei (1962) (Zweifach et al, 1958) sterilized the gut of dogs before subjecting them to haemorrhagic shock. This did not alter the course of irreversibility. At the same time, Fine (1952, 1955, 1962) reports better results in dogs pretreated with non-absorbable oral antibiotics, if given prior to the induction of haemorrhagic shock. He claims antibiotic treatment pre induction of shock increases the survival rate from 20% to 65%. Yet out of 192 blood cultures taken at intervals

during shock up to the time of death, only four positive cultures were found: two for clostridia and two for pseudomonas (Powers and Schloerb, 1958). Intestinal extirpation of the dogs prevented the plasma sequestration and 'pooling' into the intestine that follows bacteremic or endotoxin shock.

Lillehei (1957), Lillehei and MacLean (1958) and Fine et al (1959), while they disagree on the bacterial etiology of every form of shock, agree that the late phase of irreversible shock is probably mediated by bacterial endotoxins which cause the vascular changes that contribute to the irreversible phenomenon and then finally to the death of the animal.

Ravin (1958) and his co-workers have demonstrated the presence of endotoxin activity within 5-10 minutes of irreversible haemorrhagic shock.

Lillehei (1956) demonstrated that perfusion of the superior mesenteric artery either with or without an Eck fistula, thus perfusing the small bowel at near normal pressure, was more effective in preventing irreversible haemorrhagic shock than perfusion of the liver. The dogs which survived permanently did not show the mucosal congestion and necrosis which were noted in the control animals. Lillehei (1958) also claims that a 'hemin' pigment is present in higher concentration in the plasma of non-survivors than in the survivors and the pigment increases coincident with the development of irreversibility.

Deuterium oxide studies with endotoxin shocked dogs showed that the intestine and the liver took up sufficient deuterium

oxide from the blood in two minutes. This is consistent with the sequestration of plasma previously mentioned, that is noted in endotoxin shock (Bradle and Johnson, 1958). In their studies, they also demonstrated that after endotoxin administration, the normal flow rate value for the intestine was reduced from 1.2 ml./min./gm. to 0.4 ml./min./gm. This perhaps explains the basis for the necrotic haemorrhages of the small intestine in irreversible haemorrhagic and endotoxin shock.

The mucosal haemorrhagic necrosis which is seen in dogs dying from irreversible haemorrhagic and endotoxin shock can be compared to the pseudomembranous enterocolitis which occurs in some patients dying from various disease entities associated with shock (Penner and Bernheim, 1939a, 1939b). These authors conclude that pseudomembranous enterocolitis may be a sequellae of vascular spasm encountered during shock. This entity is not due to antibiotic therapy, since it was described before the advent of antibiotics. It must be concluded therefore that necrosis of the intestine may occur in shock just as it does in the kidney (Penner and Bernheim, 1939a, 1939b).

Ende (1958) reported several cases of intestinal necrosis in patients dying of severe heart failure and shock who at post mortem had no demonstratable mesenteric thrombotic vascular occlusion. Gastrointestinal mucosal ulcerations, the so-called stress ulcers (Boyd, 1961) and haemorrhages are a common finding at post mortem following severe shock.

Franco-Bowder (1959) and his associates working on a potent histamine liberator, polymixin B., induced mucosal haemorrhages and

erosions similar to those encountered in endotoxin and haemorrhagic shock. These authors concluded that histamine release from the peripheral body stores is the primary cause of vascular disturbances, which result in the intestinal lesions. In the monkey, which is much closer to man than the dog, intestinal haemorrhagic necrosis is rarely seen in endotoxin shock (Vick et al, 1963).

"It would seem that the small bowel is the locus minoris resistance during haemorrhagic and endotoxin shock. The additional intraluminal loss of blood and plasma as a result of peculiar susceptibility of the intestinal capillary bed to ischemia appears to be one of the significant lethal factors in haemorrhagic 'shock'". McRay (1958).

6. RENAL HEMODYNAMICS DURING SHOCK

Impairment of renal function is a common clinical finding which is associated with the shock syndrome. Anuria, proteinuria, oliguria, azotemia, uremia and sometimes hematuria are a reflection of severe disturbances in renal function (Bywaters, 1944), (Van Slyke, 1948), (Corcoran, 1943, 1945, 1947a, 1947b). These findings are commonly encountered in patients with bacteremic and haemorrhagic hypotension. Under normal conditions estimated blood flow to the kidney is 20-25% of totalcardiac output (Selkurt, 1945, 1946). On account of its copious blood supply and its labile vasomotor activity, the kidney plays an important role in homeostasis of the circulatory system.

The hypotension that occurs in shock leads to renal ischemia, which is probably the cause of the renal changes (Malcolm, 1905).

Hypotension causes reduction in renal blood flow (Moyer et al, 1955), (Cameron, 1962), (Wiggers, 1950), which in turn is accompanied by a decrease in glomerular filtration rate (G.F.R.). The excretion of potassium, inorganic phosphate and lactate is also severely impaired. These physiological derangements are accompanied by metabolic acidosis, since the increased production of acids cannot be compensated by their excretion and formation of ammonia to conserve base (Wiggers, 1950), (Cannon, 1917), (Wilson, 1963), (Clowes, 1961), (Crandell, 1959).

It is possible that some substances unrelated to the renin-angiotonin system (Corcoran, 1943), (Chambers and Zweifach, 1947) are rapidly liberated from the blood following endotoxin injection. These substances may be responsible for the renal vaso constriction within the first hour of endotoxin circulation (Wiggers, 1950). Increase in renin substrate of dog's blood increases after haemorrhage. (Hamilton and Collins, 1941, 1942), (Sarpestein et al, 1941, 1942), (Huidobro and Braun - Mendez, 1942), (Rau, 1949).

Franklin (1951) postulated that the vasoconstriction of the renal circulation which occurs is preferrential treatment of the brain and the heart. Histamine-like substances may be responsible for the kidney hyperemia, the persistent fall in systemic arterial blood pressure and the gradual decline in peripheral resistance (Vassant et al, 1963), (Spink, 1961), (Hinshaw and Bradley, 1959), (Hinshaw et al, 1957, 1961).

A proteolytic enzyme may be released from the juxtaglomerular apparatus or from the cortical epithelium. The enzyme, by reacting

with plasma globin forms angiotonin (hypertensin) (Wiggers, 1950). This results in tubular reabsorption depression (Pickering and Prinzmetal, 1940). Trip and Ogden (1948) believe that this vasoconstrictor substance is a byproduct of angiotonin.

Default of renal excretory mechanism seems to be the most important factor in man in the production of irreversibility in shock (Vick et al, 1963). Hinshaw and Bradley (1959) also working on clearance tests, observed the temporary decline of excretion ratios after administration of endotoxin. This temporary decrease suggests depression of renal tubular function secondary to vasoconstriction. The Tm P.A.H. values returned to preendotoxin levels while creatinine ratios showed irregular changes. The same investigators noted a fall in weight of the kidney after endotoxin injection (Hinshaw and Bradley, 1957). Other investigators (Selkurt, 1945, 1946), (Corcoran and Page, 1943, 1947), (Lawson et al, 1944), (Phillips et al, 1945), (Montague and Wilson, 1948), using clearance techniques have demonstrated impairment of renal blood flow during shock.

Blood studies on A. V. oxygen differences during haemorrhagic shock do not show any change; renal veins stay well oxygenated till the terminal phase of shock (Wiggers, 1950). Even when the glomerular filtration rate is less than 10% of normal, extraction ratios of para-amino-hippurate are maintained (Vick et al, 1963). Suprarenal aortic occlusion for eight hours in the African green monkey resulted in acute renal failure and yet the animals survived up to seven hours of haemorrhagic hypotension with no significant

renal sequellae (Cerilli et al, 1962).

On the other hand, Selkurt (1945a, 1945b, 1946) by clamping the renal vessels during haemorrhagic shock produced damage to the kidney tubules. The pathophysiological changes ranged from hydropic degeneration to parenchymatous (Moon, 1947) degeneration of renal tubules. In clinical shock these changes are heralded by scanty dark concentrated urine, containing albumin, hemoglobin, epithelial and red cells, as well as hyaline granular and pigmented casts (Martineau and Hartman, 1947).

As shock progresses to irreversibility, hemolysis and liberation of myoglobin takes place. This is more commonly encountered in shock arising from burns and crush injuries. The myoglobin is deposited into the kidney tubules. Such deposition may lead to complete blockage of nephrons and ultimately to circulatory failure (Bywaters, 1944), (Corcoran et al, 1943), (Corcoran and Page, 1943, 1945, 1947).

7. METABOLIC CHANGES

a) Carbohydrate Metabolism

The hypoglycemia that is encountered in endotoxin and haemorrhagic shock has been already mentioned. The interference in the functional efficiency of the enzyme systems concerned in oxydation, such as cytochrome oxidase and the succino-oxidase system is partly responsible for the derangements of carbohydrate metabolism during shock.

As the hypoxia continues, the ability of the liver to remove

lactate falls progressively and the arterial level of the lactate rises accordingly (Beatty, 1945). There is also an elevation of inorganic phosphate, lactic acid and depleted glycogen, A. T. P. (adenosinetriphosphate), phosphocreatinine and an abnormal accumulation of phosphopyruvic acid (Lepage, 1946). Beatty also found that in severe haemorrhage there is increase in the amount of glucose released by the liver, and in the arterial glucose level in spite of the rise in peripheral glucose utilization (Russell et al, 1944). The shift to anaerobic metabolism may lead to faulty energy production with breakdown of high energy organic phosphorus compounds to inorganic phosphorus (Engel, 1952). The most important factor which initiates this anaerobic metabolism during shock is tissue anoxia (Wilheim, 1948).

It is reasonable to postulate that the extraordinarily high lactic acid and low arterial pH that occurs during haemorrhagic shock may combine to upset the vital enzymatic processes. This may contribute eventually to cellular disorganization and death (Russell et al, 1944). The same authors think that the integrity of the enzyme systems is not seriously damaged since they show a rapid return to normal following transfusion. The development of irreversibility in haemorrhagic shock is not due to failure of the liver to metabolize lactic and pyruvic acids (Russel et al, 1944), (Drucker et al, 1958). When death occurs, it seems to arise from disorganization of the cellular and enzymatic processes (Drucker et al, 1958).

The return to normal (Seligman et al, 1947) of lactic and pyruvic acid after transfusion is interpreted as indicating that

metabolic acidosis is not the primary cause of irreversibility. Neverthe less, many investigators believe that while acidosis per se does not cause irreversibility, it is an important contributory factor since administration of alkalinizing agents increased the survival rate of dogs subjected to prolonged haemorrhagic shock (Levine et al, 1944), (Cannon, 1918), (Hardaway, 1961,,1962), (Milroy, 1917), (Wiggers and Ingram, 1946).

b) Protein Metabolism

Some of the metabolic disturbances of protein have been discussed. Each tissue metabolizes protein in its own fashion and there are differences in anabolic and catabolic rates amongst various tissues (Levenson et al, 1959). As a result of plasma loss in untreated haemorrhagic shock, hypoproteinemia occurs. There is increase in total free amino nitrogen during shock (Sayers et al, 1945), (Engel et al, 1943), (Russell et al, 1946).

An early rise in the level of amino nitrogen during haemorrhagic shock is indicative of a poor prognosis (Sayers et al, 1945), if the animal is not treated. As the animal progresses into shock, there is increased release of amino acids from muscle and other organs which are damaged as a result of reduced circulation. As the liver fails in metabolizing nitrogenous compounds, aminoacidemia takes place.

There is a release of various peptides and activation of certain proteolytic enzymes which are probably released from the muscle (Levenson et al, 1961). In severe late shock, elevation of blood ammonia is commonly observed (Cowley et al, 1960),

(Nelson and Seligson, 1953). This rise is partly due to hydrolysis of urea in the gut, absorption of the ammonia into the portal blood and decreased ability of the liver to form urea.

c) Tissue Metabolites

Tissue concentrations of glycogen, adenosine triphosphate, and phosphocreatinine were analysed (Wiggers, 1950). Samples were drawn from the liver, the kidney, brain and heart muscle. There was no depletion of these substances in the brain and muscle. The heart showed slight depletion of energy reserves, while the kidney and liver showed serious depletion. The conclusion drawn is that during shock, there is a preferential distribution of blood to the heart and the brain at the expense of the kidneys and the liver (Lepage, 1946).

The metabolic changes seen in shock may be a reflection of changes in the mitochondria of cells (Croxatto et al, 1951). There is claim that enzymatic hydrolysis of the peptides leucylglycine, leucyldiglycine and leucinamide acetate are increased following haemorrhage and traumatic shock in dogs and cats (Levenson, 1951). There is also a corresponding rise in lactic acid dehydrogenase (Vessell et al, 1951).

d) Acid Base Balance and Electrolytes

Hypovolemic shock is accompanied by reduction in alkali reserve, a marked metabolic acidosis (Cannon, 1919), (Milroy, 1917), (Wiggers, 1950) and a development of oxygen debt (Guyton, 1961). This metabolic acidosis is due to an increase in blood lactic and other organic acids. The reduction in the tissue perfusion leads to

anaerobic respiration which leads to accumulation of metabolites and a further reduction in alkali reserve. This leads to reduction in pH and an increase in plasma catecholamines (Manger et al, 1957). Animals treated with THAM: tris (Hydroxymethyl) aminomethane (Page and Olmstead, 1951) had a greater survival rate (Hardaway, 1962) than animals treated with saline alone (Smith and Moore, 1962). These authors observed that saline administration in highly acidotic dogs produced little change in the animal's acid-base status. There was, however, a fall in the serum potassium level in 75% of the dogs. Dextrose in water infusion showed no change in potassium, chloride and sodium levels.

Levine (1944) reports 62% survival rate in haemorrhagic shock animals treated with sodium bicarbonate supplemented with whole blood transfusions, while treatment with whole blood alone yielded 25% survival. All the control animals died.

In Hardaway's group (1962), the highest survival rate was observed when correction of the arterial blood pH was associated with oxygen delivery. Catecholamines were highest in those animals which did not receive buffer, indicating that acidosis per se in addition to hypotension may stimulate catecholamine production.

Acidosis which appears during haemorrhagic and endotoxin shock is not a direct cause of irreversibility, since its correction does not seem to prevent the irreversible trend (Hardawayet al 1962)(Cannon 1918)(Russell et al 1963).

The rapid metabolic acidosis which develops in haemorrhagic and endotoxin shock is partially compensated by a reduction in partial pressure of carbon dioxide in the blood (Hardaway et al 1962), (Root et al 1947), (Guyton 1962). Metabolic acidosis correlated well with survival and could be used as an effective criteria for prognosis (Root et al, 1947).

Electrolyte disturbances are known to occur during haemorrhagic and endotoxin hypotension. There is marked increase in plasma potassium due to movement of intracellular fluid into the blood stream to replace the fluid volume lost through haemorrhage. Plasma potassium may also rise as a result of cellular release of potassium associated with glycogen and protein tissue breakdown (Baetjer, 1935), (Zwemer and Scudder, 1937), (Root et al, 1947). The potassium levels reach their highest levels in eight hours. The more severe the haemorrhage, the higher the serum potassium concentration. Zwemer (1937) believes that histamine has something to do with increased potassium levels in the blood during shock, since injection of histamine is followed by increased potassium levels in extracellular body fluids. During hyperventilation, there is a drop in potassium levels (Hall and Reeser, 1963).

The high levels of serum potassium exert toxic effects on the heart (Manery and Solandt, 1943). Winkler et al (1938) noted during shock only minor electrocardiograph changes of potassium intoxication. These authors maintain that it is exceptional for death to be caused by cardiac arrest resulting from potassium auto-intoxication. They feel that such high toxic serum levels occur only pre-mortem. The tonic effects of potassium may be aggravated by hypocalcemia and acidosis which may be seen in shock (Levenson, 1961).

Plasma sodium and chloride may be normal or low during the early phase of shock. At this stage, sodium and chloride excretions are initially low, while potassium execretion is high. Sodium tends to accumulate in the injured tissues (Tabor et al,

1951). As the potassium leaves the cell, sodium and hydrogen enter, resulting in hyponatremia. Sodium and hydrogen immigration into the cell may also be accompanied by basic amino acids such as lysine (Fuhrman, 1960).

8. NEUROHUMORAL AND ENDOCRINE ASPECTS OF SHOCK

a) Miscellaneous Neurohumoral Substances

Any form of injury to the nervous system such as concussion, as well as prolonged hypotension, was found to lead to failure of the pressor response to angiotonin (Fine, 1961). Cannon and Rosenblueth (1937) found that denervation of animals in shock greatly augmented response to a variety of drugs. Treatment of animals with adrenergic blocking agents increased the rate of survival in animals subjected to shock (Wiggers, 1950). Nickerson and Carter (1959), using a Noble-Collip Drum, found that the vasodilator Hydralazine reduced the incidence of acute traumatic death, while Dibenzyline increased the overall survival, whether trauma was mild or severe.

Acidosis and hypoglycemia, as discussed before, are known to accompany shock (Cannon, 1918). Elevation of lactic acids and glucose is mediated by increased catecholamines in the plasma of shocked dogs (Fine 1961). The reduction of arterial pH is followed by depression of CO_2, which results in depression of ventricular isometric systolic tension. There is a corresponding decrease in the vessels' response to norepinephrine (Derby et al, 1960).

Page (1961) demonstrated that forced breathing of CO_2 produced hypotension and severe vascular refractoriness in dogs. Total sympathectomy prevented this refractoriness. It seems that CO_2 is a powerful stimulator of the autonomic ganglia.

It is postulated (Fine, 1961), (Wiggers, 1950), that humoral agents control vasomotor and venomotor tone of the peripheral vessels during shock. These same investigators believe that rhythmic contractions of the vascular smooth muscle or release of local substances may also be responsible for the adjustment of vascular tone during shock.

It is possible that some substances besides epinephrine and norepinephrine may be responsible for the vascular phenomenon. Environmental change of pH may be equally important in regulating peripheral vascular tone.

The kidneys, in response to a variety of stimuli, including haemorrhage, release some vasoconstrictor substances (Huidboro and Braun-Mendez, 1942). The same authors claim that the proteolytic enzyme renin is freed to act on alpha - 2- globulin to produce angiotensin, which has a powerful effect on vascular tone. Even CO_2 concentration can effectively change vascular tone. The sodium cation has been clinically noted as the chief offender in maintaining or increasing vascular tone in hypertension.

It is possible that these vasoactive substances have injurious effects to both peripheral vessels and the heart. In the plasma of shocked animals, other unidentified vasoconstrictor substances may be present (Page, 1961). Weinstein et al (1960)

identified what they considered to be a vasopressin in the blood of dogs subjected to haemorrhagic shock.

Freiden et al (1954) found that their hypophysectomized animals were extremely vulnerable even to slight haemorrhage. Administration of pitressin returned susceptibility to haemorrhage back to normal.

Angiotensin, synthesized at Cleveland Clinic and Ciba Pharmaceutical Co., is another vasoactive polypeptide whose pharmacological effects in shock are still under investigation (Page, 1961). Proteases liberated during tissue injury may be responsible for liberation of these vasoactive substances.

Sarpistein (1941) found that blood of normal animals with normal blood pressure contains activator with no renin, whereas post haemorrhage blood taken after long persisting low pressure contains demonstrable amounts of renin. These findings support the views that the kidney acts as an organ of internal secretion in order to preserve the homeostasis of the whole circulatory system by humoral mechanism (Levenson, 1961).

b) Epinephrine

It has already been pointed out that shock, fear and other situations of stress lead to an increase in production of catecholamines. In haemorrhagic and endotoxin shock the amount of endogenous circulating catecholamines becomes markedly increased (Corday, 1960), (Cameron, 1962), (Wiggers, 1950), (Longerbeam, 1962), (Harkins, 1935, 1941a, 1941b, 1941c). Watts (1956) is of

the opinion that the amount of endogenous catecholamines may be as high as 29 micrograms/l., decreasing to 7 micrograms/l. after restoration of the blood volume to normal by reinfusion. In spite of normovolemia and reduction in circulating catecholamines, the animals still went into irreversible shock and died (Greever and Watts, 1959).

Corday et al (1960) found that the peripheral levels of norepinephrine increased to a much greater extent than those of epinephrine, while epinephrine levels in adrenal vein plasma were more than the norepinephrine levels. This finding seems to indicate that the main source of norepinephrine level in the peripheral blood was extra adrenal, possibly sympathetic nerve endings. They postulated that the high peripheral norepinephrine levels may be due to decreased utilization, rather than due to activity of an extra-adrenal source.

Although there was no evidence to demonstrate adrenal cortical insufficiency during shock, necropsy findings have revealed that sequential histological changes develop in adrenal glands of animals and humans who have died as a result of various types of shock (Blalock, 1934), (Dunphy et al, 1941), (Davis, 1941, 1949),(Moon, 1942). In those animals that succumbed to shock comparatively early, petechial haemorrhages were found in the medulla and in the Zona reticularis and Zona fasciculata of the cortex (Wiggers, 1950). After a prolonged state of shock, focal necrosis and leucocytic infiltration have been reported (Selye, 1946). It is difficult to conclude as to whether these pathological changes are the cause or the consequence

of the circulatory failure responsible for death. Irreversible haemorrhagic shock can develop without any demonstrable histopathological changes in the adrenals. The author autopsied twenty dogs which had died in irreversible shock and no macroscopic or microscopic lesions were found in the kidney and the adrenals.

What part the adrenals play in the mechanism of shock is still not clear. Walker et al (1959) claim that they found increased corticosteroids in the adrenal veins of dogs subjected to acute blood loss.

c) Histamine

Histidine decarboxylase activity of certain animal tissues can be increased by stress, by injection or release of epinephrine or norepinephrine or by injection of E. Coli endotoxin - evidence pointing to an increase in the rate of histamine synthesis in the living animal (Schayer et al, 1960). These observations strongly suggest the hypothesis that histamine and the catecholamines form a balance concerned with circulatory homeostasis under conditions of stress and that a sufficient excess of either of the antagonists may lead to circulatory collapse. The events observed in the small blood vessels during shock support this hypothesis. There are similarities between the vascular actions of histamine and endotoxin (Kuida et al, 1958), (Gillbert et al, 1958), (Hinshaw et al, 1959), (Lillehei and MacLean, 1958), (Aust, 1959), (Dale 1929), (Hardy, 1959), (Stead and Warren, 1944).

The activity of histidine decarboxylase is increased by endotoxins. These observations suggest that the rate of histamine synthesis is accelerated in this kind of shock (Schayer, 1960a, 1960b). In addition, it is found that the stimuli such as stress, epinephrine, endotoxin, also lead to increased activity of the enzyme, which synthesizes histamine; the likelihood that histamine is an important shock toxin seems very strong. Schayer (1960a, 1960b) found that catecholamines increased the activity of histidine decarboxylase.

d) Serotonin

This neuroendocrine hormone is also associated with argentifinomas and it is a powerful vasoconstrictor (Walton, 1959). It is liberated from platelets. It seems that during haemorrhage, serotonin has a beneficial effect of causing an injured blood vessel to contract down on a forming platelet clot (Page, 1961). The role of serotonin during shock is not clear. It may be that this substance is a precursor or a more primitive form of epinephrine and norepinephrine.

e) Bradykinin

Bradykinin seems to be liberated during shock. This substance has been recently synthesized and it seems besides its pressor effects, to cause increased capillary permeability. The author observed during endotoxin shock a period where bradycardia was very marked. This usually occurred 5 - 30 minutes after administration of endotoxin. Goodwin and Richards (1960) found in the blood of protozoa-infected

animals a substance which was similar to polypeptides. The substance may arise from host parasite reaction.

f) Heparin

Hypercoagulability of the blood, which occurs in shock, has already been discussed (Crowell and Read, 1960), (Crowell, 1960). Large doses of heparin have been known to protect dogs from irreversible shock (Crowell and Read, 1955), (Crowell, 1960), (Hardaway et al, 1959, 1962).

9. PRESENT CONCEPTS ON THE TREATMENT OF SHOCK

a) Vasopressors

Vasopressors have been used in the treatment of shock for many years. However, at the present moment, controversial evidence regarding the efficiency of vasopressor agents in shock, is accumulating. During haemorrhagic shock or any form of stress, the body pours out its own endogenous catecholamines (Corday, 1960), (Cameron, 1962), (Wiggers, 1950), (Close, 1958), (Wiggers and Ingram, 1948), (Longerbeam, 1962), (Lillehei and MacLean, 1958), (Bronson et al, 1957), (Zweifach, B.W., et al, 1956). These workers argue that although initial vasoconstriction offers temporary benefits by augmenting the amount of blood which can be lost before critical changes in the blood pressure occur, there can be little doubt that the prolonged continuance of sympathogenic constriction is deleterious in that it accelerates the onset of the irreversibile state.

Clove et al (1957) claim 65% mortality rate in haemorrhagic shock dogs treated with norepinephrine as compared to 33% in controls. Vassant, Weil et al (1963), working on patients with bacteremic shock found that arterial resistance and not vasodilation was the underlying cause of reduced venous return. They also questioned the wisdom of using vasopressor agents, since their use would result in additional vasoconstriction. Administration of metaraminol in endotoxin shock to maintain 'normal' blood pressure enhanced the fatal reaction of the animal to endotoxin (Lillehei and MacLean, 1959).

Aramine (metaraminol bitartrate) may temporarily improve an increase of flow through the myocardium, but there is no correction of the carbohydrate metabolic disturbances that occur during hypotension and oligemia. Transfusion seems to correct some of those disturbances. Correcting the hypotension alone for which the vasopressors are principally used does not seem to accomplish much good. This supports the concept that hypotension alone is not necessarily harmful to the heart (Catchpole, 1955). Severe hypotension induced by spinal anesthesia produces no evidence of myocardial anoxia or gross metabolic derangements in human subjects (Hackel, 1960), (Hackel and Goodale, 1955).

Each organ has a characteristic vascular response to endogenous or exogenous catecholamines. Catchpole (1955) found that l-norepinephrine decreased coronary vascular resistance which was already decreased in haemorrhagic hypotension. Corday (1960) found that levarterenol caused increase in coronary flow above control values and peripheral coronary resistance diminished markedly.

The administration of sympathominetics causes a marked drop in the portal vein circulation. On the whole, total hepatic flow is diminished because the blood supply to the liver at this time becomes principally arterial in origin. Brunson et al (1957) believe that the incidence of liver necrosis has increased in the last ten years because of the extensive use of vasopressor drugs. The liver shows central necrosis, which is known to occur in shock alone. Other investigators (Braude et al, 1953), (Borden and Hall, 1951), (Hall and Gold, 1955), have found a high correlation between hepatic necrosis and the administration of sympathomimetic amines. Corday (1960) does not accept this concept, since 70% of the oxygen supply to the liver is supplied by the hepatic artery and flow of this vessel is almost equal to the normal flow after levarterenol administration.

Reduction of systemic blood volume is followed by reduction in renal blood flow with increased vascular resistance. Restoration of renal circulation to normal by levarterenol leads to further reduction in blood flow and increase in vascular resistance (Corday, 1960), (Watts, 1956), (Livesay et al, 1954). However, when small doses of epinephrine or levarterenol were administered, the excretion of urine increased, whereas large doses of these drugs led to reduction in the volume of urine (Langston and Guyton, 1958). Necrosis of the kidney following severe haemorrhagic and traumatic shock have been substantiated in man (Penner, 1940), (Sheehan, 1947, 1950), (Duff, 1941), (Lucke, 1946), (Bywaters, 1944), (Corcoran and Page, 1947), (Van Slyke, 1948), (Oliver et al, 1951).

The decrease in flow and increase in vascular resistance is disproportionally large in renal and splanchic circulations. The possibility that vasopressors may aggravate the ischemia of the intestine already produced by the shock cannot be ignored (Cone et al, 1957). These authors have recently reported the occurrence of intestinal necrosis in a young child with a pheochromocytoma, who died in hypertensive crisis. These observations support the theory that high concentration of catecholamines in the circulation exert deleterious effects on the gut and other organs. Penner and Bernheim (1939) produced ulcerations of the digestive tract in dogs by repeated injections of epinephrine.

Stimulation of the splanchnic nerve and injection of epinephrine and norepinephrine all produce vasoconstriction of the mesenteric vascular bed (Deal and Green, 1956), (Levy, 1958). Even sympathetic stimulation alone has been shown to produce mesenteric vasoconstriction (Bunch, 1898), (Bayliss and Starling, 1899), (Grayson and Swan, 1950).

Hardaway (1962), who has done some extensive work on coagulation of the blood during shock, observed that norepinephrine causes hypercoagulability of the blood, which leads to tissue anoxia, tissue necrosis and eventually to the irreversible phenomenon.

In spite of the growing evidence against the indiscriminate use of sympathomimetic drugs in the treatment of any form of hypotension, clinical evidence of the beneficial effects of vasopressors cannot be ignored (MacLean, 1962). The good effects of vasopressors resides in their ability to increase the perfusion of vital organs,

improve the venous return, (Rasking, 1953), (Shadle, 1955), (Weil, 1956), and enhance the myocardial function by increasing coronary flow and sometimes by direct stimulation of the myocardium itself (Lansing et al, 1962).

The increase in venous return to the heart with concommitant increase in cardiac output effected by sympathomimetics has been established experimentally (Rasking, 1953), (Shadle, 1955), (Weil, 1956). The vasopressors may also have a dilating effect on hepatic veins (Andrews, 1955). Catchpole (1955) and his co-workers claim that norepinephrine decreases coronary vascular resistance in haemorrhagic shock dogs and increase coronary blood flow. It seems according to these authors that sympathomimetics have a physiological action on the heart, the kidneys and the liver, especially in a patient with bacteremic shock. Norepinephrine used to treat haemorrhagic shock refractory to blood replacement has been employed with encouraging success (Lansing and Stevenson, 1958), (Lansing et al, 1957).

The use of vasopressors early in shock before vasomotor collapse has taken place and in dosages that maintain blood pressure just below normal has satisfactory results (Corday, 1960),,(Lansing et al, 1962). In cases where loss of blood is the initiating cause of shock syndrome, vasopressors alone cannot be used as substitutes for blood replacement. Epinephrine alone in the treatment of olegemic shock is not effective because it does not correct the metabolic abnormality while concurrently imposing a heavier burden

of work on the heart due to further increase in vascular resistance (Caliva et al, 1959). "Successful restoration of the blood pressure by a vasopressor must not be the signal for a period of complacency." (Lansing, 1962).

b) Ganglionic Blocking Agents

Vasoconstriction in response to sympathetic nervous system hyperactivity as cited before, may play a deleterious role in the development of the shock syndrome.

Nickerson and Carter (1959) have demonstrated rather convincingly that pretreatment of dogs with vasodilators may increase the percentage of animals surviving various procedures designed to induce shock. Zingg (1958) using his own method of inducing haemorrhagic shock and pretreating the experimental animals with .5 mg/kg hydralazine, claims 66% permanent survivors and 30% in the controls. Baez et al, (1952) claims 100% survival rate in dibenamine pretreated animals subjected to haemorrhagic, traumatic and endotoxin shock, while only 37.5% of his controls survived. On the whole, a significant increase in the survival rate of animals subjected to haemorrhagic, traumatic and endotoxin shock has been demonstrated by many investigators using different forms of vasodilators and ganglionic blocking agents (Hakstian et al, 1961), (Baez et al, 1952), (Beck, 1956, 1959), (Carruthers and Crowley, 1956), (Hershey et al, 1955), (Inglis et al, 1959), (Jacob et al, 1956), (Gourzis et al, 1961), (North et al, 1951), (Saltz, 1960).

Vick (1963) and his co-workers in studying the relative value

of hydrocortisone, metaraminol (aramine) and phenoxybenzamine (Dibenzyline) on endotoxin shocked monkeys and dogs found that Dibenzyline dramatically reversed the renal functions when given after the onset of shock. While aramine and hydrocortisone maintained the arterial blood pressure for a long time, they did not greatly influence renal hemodynamics.

Vasoconstriction in the presence of haemorrhage gives preferential treatment of blood supply to the vital centers, the heart and the brain. In sympathectomized animals, such preference is lost. All tissues of the body are accorded the same treatment as long as the vital centres receive sufficient blood supply. All tissues of the body probably receive an adequate amount of circulation and the aggravation of the shock condition is prevented (Freeman et al, (1938). Ganglionic blocking agents work on the same principle.

Baez (1958) and his associates postulate that the protection afforded by Dibenzyline may be due to changes it induces at a cellular metabolic level besides its sympatholytic action.

Chlorpromazine, another ganglionic blocking agent, has been shown to prolong the survival time of dogs in irreversible shock (Inglis et al, 1959). This group also observed increased mesenteric circulation after administration of chlorpromazine. The importance of mesenteric circulation in the irreversible phenomenon has already been discussed.

It was also noted that animals pretreated with ganglionic blocking agents showed less blood/kg. in the reservoir compared to the control group. This may mean that pretreated animals may reach

standard levels of hypotension with less blood loss than controls (Zingg, 1958).

c) Hydrocortisone and Corticosteroids

What part cortisone plays in haemorrhagic and endotoxin shock is still a matter of speculation. Administration of cortisone in pharmacologic dosage produces a decline in arterial pressure and an increase in cardiac output (Lillehei and MacLean, 1959) in patients with shock.

> Thus the beneficial effects of corticosteroid in the treatment of bacteremic shock may be due to increase in systemic flow which is accomplished without the penalty of added vasoconstriction.
>
> (Vassant, Weil et al, 1963).

Dibénzyline and corticosteroid seem to be synergistic in this regard of increasing cardiac output with vasodilation and thus improve tissue perfusion. Kurland and Freedberg (1951) observed a potentiation of pressor response to norepinephrine in normotensive patients after administration of A.C.T.H and cortisone. These authors conclude that hydrocortisone has a protective effect against lethal tissue-damaging effect of endotoxin. Some investigators (Zweifach, 1952), (Fritz and Levine, 1951), have demonstrated that in adrenolectomized animals, vascular response to norepinephrine is lost and it is restored only by topical application of adrenal extracts or by injection of cortisone. On the other hand, Hayes (1954) is of the opinion that in haemorrhagic shock there is a decreased minute volume of blood delivered to the kidneys and presumably to the adrenal glands, with a subsequent possible

reduction in the amounts of adrenal corticosteroids available in the circulation per unit time for peripheral tissue utilization.

However, nobody has yet demonstrated conclusively reduction in steroid output during hypotension. Since massive doses of cortisone are required to produce any substantial effects, it is quite likely that the levels of circulating corticosteroids are inadequate to maintain a satisfactory vascular response (Conolly, 1958). Cowley (1962) and his co-workers using D. Aldosterone in dosages ranging from .05 mg/kg. body weight to .1mg/kg reduced the mortality of haemorrhagic shock dogs by 45%. They believe that aldosterone protects the animals against renal shut down and haemorrhagic enteritis. Zweifach and Chambers (1942) using histamine and trauma to produce shock, prevented capillary hyperemia by administration of cortical extracts. Some investigators believe that the corticosteroids which influence intermediary metabolism are the most effective in preventing irreversible circulatory failure (Swingle et al, 1941, 1942), (Remington, 1942).

Selye and Dosne (1940) using corticosterone, found it effective in combating traumatic shock. However, Noble and Collip (1942) did not find practical benefits of cortical compounds in shocked animals. Fine and Seligman (1942) also observed no favourable effects of corticosteroids in treatment of haemorrhagic shock. These unfavourable effects of corticosteroids on haemorrhagic shock have been reported by other investigators (Howard and DeBakey, 1951), (Knapp and Howard, 1957).

Studies on adrenal cortices of dogs dying as a result of haemorrhagic shock showed depletion of total carboxyl containing lipoid and that administration of cortisone and A.C.T.H. increased the histologic evidences of damage to the adrenal cortices of dogs in irreversible haemorrhagic shock (Frank et al, 1955).

CHAPTER III

METHODOLOGY AND MATERIALS

1. ANIMALS

One hundred and thirty-four mongrel dogs without preference to sex and weighing between 18 - 26 kg. (average 22 kg.) were used in these studies. These dogs were subjected to different conditions of haemorrhagic and endotoxin shock and were divided into four main groups:

GROUP I: DIALYSIS OF NORMAL DOGS - 10 dogs

a) 5 without prophylactic antibiotics

b) 5 with prophylactic antibiotics

GROUP II: ENDOTOXIN SHOCK

a) Endotoxin and early dialysis with old and new coils - 28 dogs

1) 14 controls

2) 14 experimental

b) Endotoxin and early dialysis with new coils only - 10 dogs

c) Endotoxin and late dialysis with old and new coils - 15 dogs

1) 5 controls

2) 10 experimental

d) Endotoxin and histamine - 6 dogs

e) Endotoxin and mechanical effects of dialysis - 10 dogs

f) Endotoxin, morphine and early dialysis, with both new and old coils - 10 dogs

GROUP III: HAEMORRHAGIC SHOCK

a) Haemorrhagic shock and dialysis - 20 dogs

1) 10 controls

2) 10 experimental

b) Haemorrhagic shock and Dibenzyline - 20 dogs

1) 10 controls

2) 10 experimental

GROUP IV: DETERMINATIONS OF NORMAL ARTERIAL CHEMISTRIES - 5 dogs

All the dogs were fasted for twenty-four hours before they were subjected to any form of experimental procedure. Dogs which did not look healthy were discarded or used as donors for the blood necessary for priming of the dialysing artificial Kolff kidney machine. All attempts were made to avoid exciting the dogs as they were being transferred from the kennels to the anesthesia room. Most technicians skilfully mastered the art of cajoling a dog to the anesthetic table with very little struggling on the part of the animal. When the dog had completely won the confidence of the operator and his team, it was weighed on Weight Model 9281 (Toledo) Scale. Then the dog was securely tied around the mouth to prevent any accidental dog bites in the laboratory.

2. OPERATIVE METHOD AND ANESTHESIA

a) Method of Anesthesia

The left antero-medial aspect of the foreleg was shaved, so as to visualize the gross anatomical position of the cephalic vein. Since some dogs became excited by the sound of the automatic electric shaving machine, time for the dog to calm down was allowed before any anesthesia was administered. All dogs except the endotoxin and morphine group (Group II, (f)) were anesthetized with 30 mg/kg of intravenous nembutal. This was cautiously injected into the left cephalic vein with an 18 gauge needle. In cases where there was accidental infiltration of the nembutal in the tissues around the left cephalic vein, the right foreleg was used. In most cases the amount of anesthesia used was less than 30 mg/kg. Injection of the nembutal was discontinued as soon as the dog showed sufficient muscle relaxation with preservation of the corneal reflex. The binder around the mouth was loosened. The dogs were shaven in both groins and painted with tincture of merthiolate 1:200.

b) Operative Procedure and Operation Room Set-up

No aseptic technique was observed in our experiments. The animals were then transported to the operation room. The experimental dog was laid in a dorsal position on the Weight Model 9281 Scale, which is calibrated in both pounds and kilograms and can be opened and locked during the experimental procedure. This scale

enabled the operator to observe the weight of the experimental animal throughout the procedure. The control dog was laid down on a separate table beside the experimental dog. This facilitated constant observation of both dogs during the experiment.

Both dogs were intubated, but no pump or Bird Respirator was connected to the tube. A thermometer probe was inserted into the oesophagus to record temperatures in degrees centigrade. In order to prevent both the probe and the intubation tube from slipping, they were tied separately around the upper jaw. The probe was sometimes snuggly tied around one of the canines, while its other end was connected to one side of the Tele-thermometer. This is so constructed that two probes, one from each dog can be plugged in at the same time on each side of the Tele-thermometer box. (Fig. 2)

When the dogs were securely tied on the tables, both the right and the left femoral vessels were dissected out and clearly exposed through a longitudinal incision one inch long, made two centimeters below the inguinal ligament. Then 3 mg/kg heparin was injected into the right femoral vein by means of a 22 gauge needle. The right femoral vein was cannulated by a polyethylene tube, No. P.330. This was pushed as high as possible to the level of the inferior vena cava for recording venous pressures in centimeters of saline. The height of this manometer was adjusted to the level of the right auricle. The right femoral artery was also cannulated and connected to a mercury manometer and occasionally, by means of a three way stop-cock, to a Sandborn polygraph,

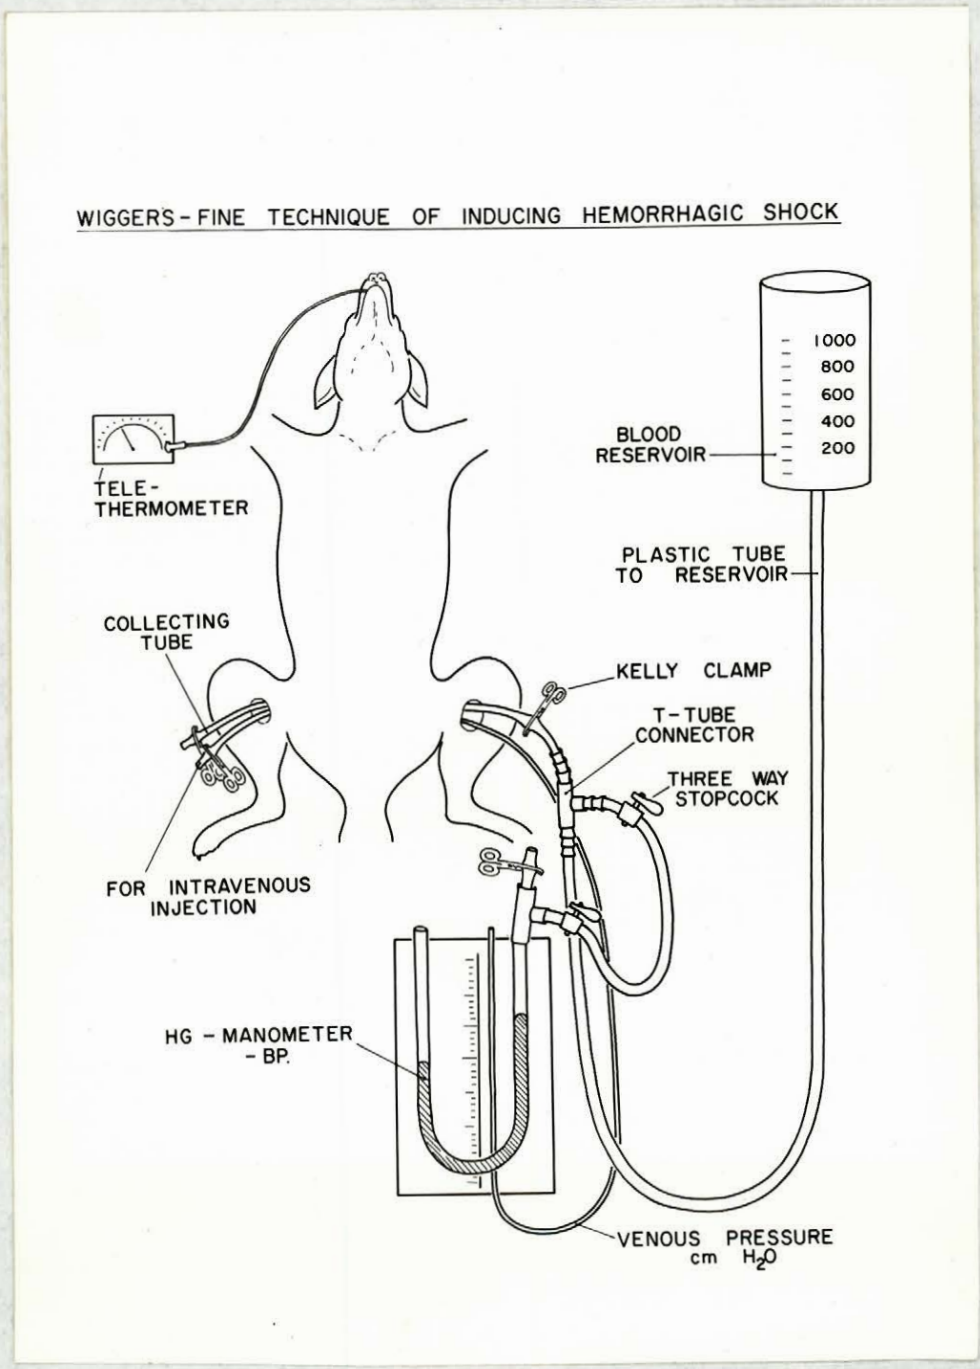


Fig. 2.--This illustrates the different apparatus used in the induction of haemorrhagic shock, using Wiggers-Fine Technique. In the case of Endotoxin shock, the reservoir was excluded from the set up.

for recording of mean arterial pressures and diastolic pressures respectively. (Photograph 2) The left femoral artery and vein were also cannulated with 'tapered' cannulae especially designed for hemodialysis tubing connections. These cannulae were first filled with normal saline to expel the air and then clamped with Kelly forceps to keep them filled with saline. Then they were inserted into the vessels. They remained clamped until hemodialysis began or when arterial samples of blood were being withdrawn. In the control dogs, the left femoral vessels were cannulated only when intravenous injections of endotoxin formed part of the experiment and when arterial blood chemistries and electrolytes were taken during the experimental period.

When all the cannulae were inserted in their proper places, the experimental dog was weighed again. It is obvious that the cannulae, Kelly clamps, the weight of the leashes and the pressure of the dog on the table all helped to increase the original weight of the dog alone. All articles on the scale contributing to this weight were recorded.

The control vital signs in both experimental and control dogs were noted. If any blood chemistries and electrolytes were studied, the control samples were taken at this period.

PHOTOGRAPH II

This picture illustrates a cannula with three way stop cock, which is connected to both a mercury manometer and a Sandborn Polygraph. A reservoir with 500 cc of blood is seen hanging on an adjustable pole at the foot of the dog. In the foreground is a tele-thermometer.

3. MATERIALS AND METHOD OF COLLECTING BLOOD SAMPLES FOR CHEMISTRIES AND ELECTROLYTES

a) The Anaerobic Method of Collection of Blood Samples for pH, pCO_2, and HCO_3

A 20 cc syringe was connected to the end of the arterial tapered cannula and 10 cc of blood was drawn and laid aside. The Kelly clamp was put back. In a few seconds another 20 cc syringe filled with 3 cc of heparin was connected to the cannula. No air was to be left in between the heparin and the nozzle of the syringe. After the syringe was connected to the cannula, the Kelly clamp was released and the arterial blood was allowed to flow slowly into the syringe. A little over 20 cc of blood was collected. Exercising every care not to introduce air into the syringe, 4 cc of blood from this syringe was squirted into a 10cc beaker. The outlet of the syringe was closed tightly by means of a special rubber cap to prevent air coming in and out of the syringe.

Meanwhile an assistant quickly pipetted 2 cc of blood from the 10 cc beaker. The blood was allowed to flow drop by drop into a centrifuge tube containing 5 cc of 11% trichloracetic acid that was kept in a refrigerator. The tube was covered with paraffin paper and taken back to the refrigerator till the lactic acid was determined. In the collection of these samples for lactic acid, avoidance of the fingers coming into contact with the delivery end of the pipette or the paraffin paper is of utmost importance. Fingers contain an appreciable amount of lactic acid.

Then finally 10 cc of the blood was drawn in a 20 cc silicone coated syringe and carefully squirted into a centrifuge tube. The assistant reinfused into the dog the first 10 cc of blood which had been withdrawn before all the blood samples were taken. After pipetting 100 mm of blood for hematocrit determinations, the rest of the sample of blood was centrifuged, and the supernatant serum used for determinations of electrolytes.

b) Hematocrit Determination

The Winthrobe method was used for the determinations of hematocrit. This consisted of filling a Winthrobe tube with heparinized blood to the 100 mm mark. This was spun at 3,000 revolutions per minute for thirty minutes. Then the height of the red cells was read and the packed cell volume expressed in percentage.

After samples for control electrolytes and chemistries were taken, haemorrhagic or endotoxin shock was begun.

4. METHOD AND MATERIALS OF INDUCING SHOCK

a) Haemorrhagic Shock

A reservoir with a capacity of 2,000 cc was employed. The inside part of the reservoir was silicone sprayed once a week. The right femoral artery was cannulated with a polyethylene tubing, 4 cm in diameter, attached to a plastic T tubing connector, one arm of which was connected to a blood reservoir, while the other was connected to a mercury manometer with a three way stop-cock. (Fig. 2)

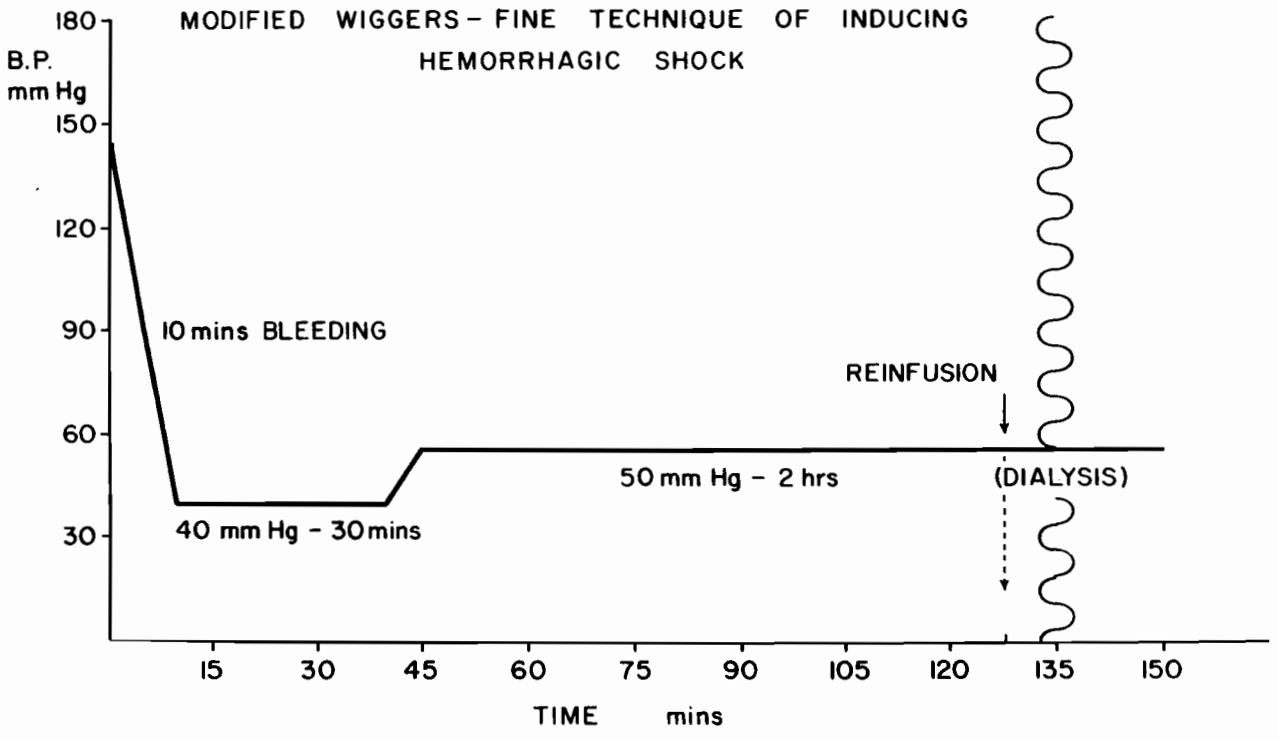

Fig. 3.--This diagram illustrates Wiggers-Fine Technique used in one series for production of haemorrhagic shock. The dog is bled into the reservoir for 10 minutes, till the blood pressure is down to 40 mm Hg. It is kept at this level for 30 minutes. At the end of 30 minutes, the reservoir is elevated, so that blood pressure reaches a level of 50 mm Hg. This level is maintained for 2 hours before reinfusion.

The tube connecting the blood reservoir with the T tubing connector is made of polyvynil material and has a bore of 8 cm in diameter. It measured 4½ yards long and thus enabled the reservoir to be elevated and lowered accordingly. A special adjustable intravenous pole for hanging the blood reservoir was used. This enabled the operator to adjust the height of the blood reservoir. Blood samples were usually collected from the left femoral artery.

In order to bring the dogs to irreversible shock, the modified Wiggers-Fine Technique was employed (Wiggers, 1950), (Fine, 1954). This method consists of bleeding the dog into a reservoir for ten minutes to bring the blood pressure to 40 mm Hg for thirty minutes. (Fig. 3) Blood pressure is maintained there by lowering or elevating the reservoir, as the case may be. After thirty minutes, the mean blood pressure is elevated to 50 mm Hg and kept there for two hours. At the end of the two hours, the blood is reinfused into the dog by means of a syringe intraarterially and then if the dog is to be dialysed, dialysis begins and is carried on for one hour.

Whenever blood samples were collected, they were drawn at 0 min., 30 min., 90 min., 150 min., 210 min., and 270 min. (See Table 4)

b) Endotoxin Shock

In this form of experimental shock, 3 mg/kg endotoxin was given intravenously for a period of one to five minutes. For the first thirty minutes, all vital signs were recorded every five minutes in both control and experimental dogs. This was done in order to avoid the possibility of missing the bradycardio-hypotensive period, which

usually occurred within five to thirty minutes after endotoxin injection. When this crucial period was over, the vital signs were recorded every ten minutes.

Blood samples for chemistries and electrolytes were collected in the same manner described above.

In both haemorrhagic and endotoxin shock, the weight of the experimental animal on the scale was determined every fifteen minutes during the course of the experiment. Weight determinations were useful. They served as a guide together with blood pressure and flow rates in replacement of fluid lost by the dog during the shock and hemodialysis periods.

Each dog received 4 mg/kg of protamine intravenously before it was sutured and taken to the recovery room.

5. PRINCIPLE OF THE ARTIFICIAL KIDNEY

This implies an exchange of two solutes through a semipermeable membrane - the blood on one side of a cellulose membrane and the rinsing (dialysing fluid) fluid on the other. (Figure 4) Diffusible substances of small molecular size, such as urea, creatinine, uric acid and phosphate freely traverse the membrane. Plasma proteins, protein-bound substances and viruses are held back.

Substances with smaller molecular weight are removed from the blood, if the volume of the rinsing fluid is large and if their concentration is greater in the blood than in the rinsing fluid. Electrolytes can pass through the membrane, guided by differences in concentration between those in the blood plasma and the electrolytes in the rinsing fluid. In this way, plasma electrolytes concentration

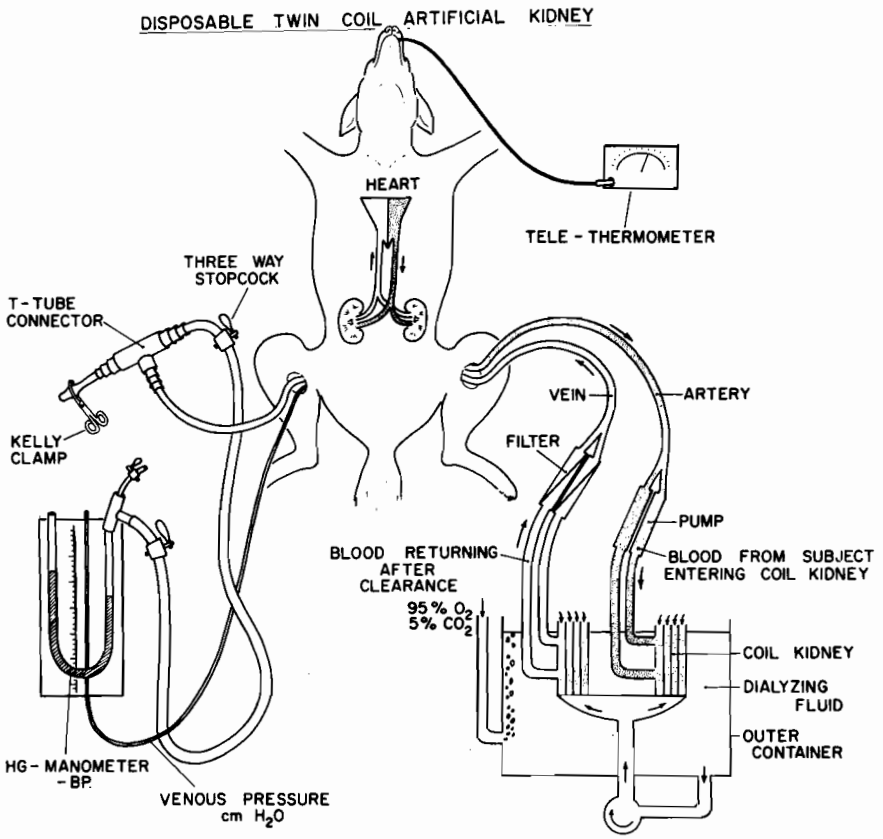

Fig. 4.--This diagram illustrates the principle and apparatus involved in the use of Kolff kidney for haemodialysis. The outer chamber, or tank, the dialyzing fluid, the inner container with the disposable coil kidney are shown on the right hand corner of the picture. The direction of the flow of blood during dialysis is shown by arrows.

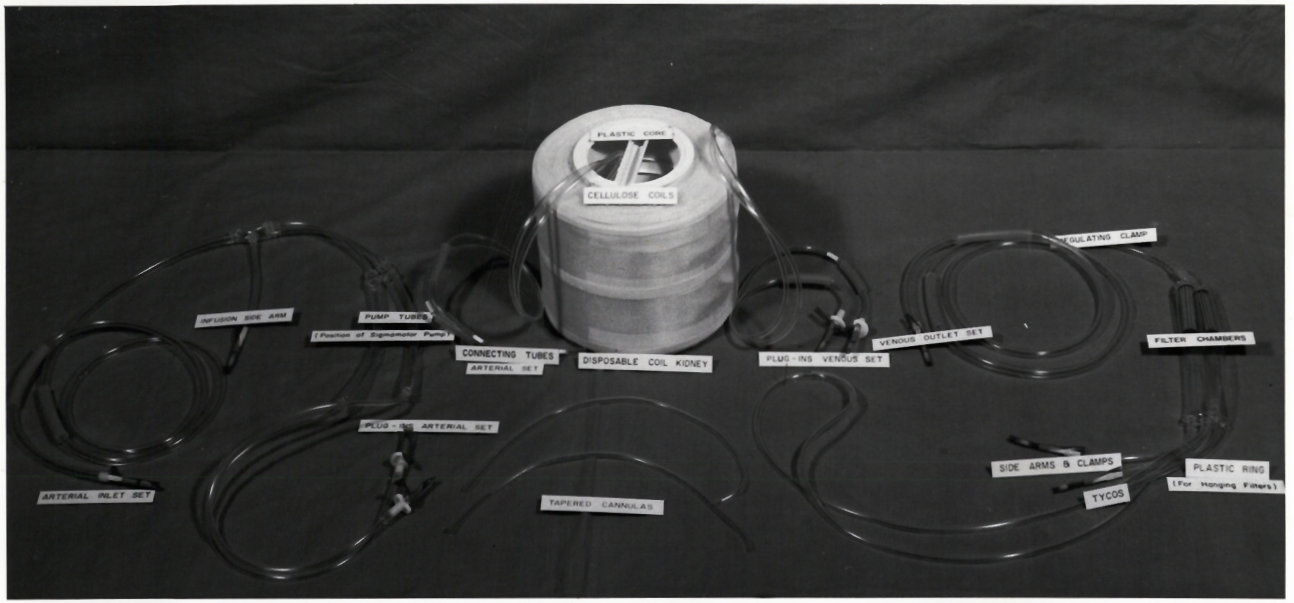
can be controlled. Dialysis can correct acidosis, hyperpotassemia or hypopotassemia within a few hours (Kolff, 1956). Acidosis in shock causes resistance of vessels to sympathomimetic drugs (Burget and Visscher, 1927). Sodium content can be adjusted to any predetermined level. Histamine and catecholamines are postulated to play an important role in the irreversibility of shock (Schayer et al, 1960a, 1960b), (Hinshaw, 1958), (Wiggers, 1950), (Harkins, 1926, 1941). Since these substances have small molecular weight, it is possible that they are dialysable. The molecular weight of histamine is 111, epinephrine 185 and that of norepinephrine is 169. Harmful bacterial products liberated during bacteremic shock may also be dialysable.

The rinsing fluid generally approaches the composition of normal plasma. The blood is usually drawn from the femoral artery and after it has been 'purified' by dialysis, it is returned to the femoral vein.

6. DESCRIPTION OF THE DISPOSABLE KIDNEY COIL

This disposable kidney coil is produced by Travenol Laboratories Inc. It is based on the kidney coil developed by William J. Kolff, of the Cleveland Clinic, Ohio (Kolff, 1956a, 1956b, 1957). The coil consists of two cellulose tubings enveloped in fiberglass screens or mesh. (Photograph 3) The fiberglass screens allow expansion of the cellulose tubes to a controlled maximum in diameter. The layers of the screens and tubing are sewn in a large roll, which is wrapped around the central cylinder. It is of interest to note that

PHOTOGRAPH III



This is the disposable Kolff kidney coil with all the tub-connections that are used during dialysis. The arterial set is on the left, while the venous one is on the right. In the centre are two tapered cannulas, which fit into the lumen of an artery, according to the size of its caliber.

when this method of dialysis was first introduced, an old fruit can was used as a central core (Kolff, 1956). There are two lengths of cellulose tubing in parallel arrangement, each measuring approximately 10.75 meters long, which is equivalent to a dialysing area of 19,000 sq. cm. This parallel arrangement makes it a 'twin' coil. Cellulose tubing has a flat diameter of 4.5 cm and the pore size of 24 angstrom. Its wall thickness is 1/1000 of an inch. The plastic central core around which both the fiberglass and the cellulose tubing are wrapped measures about 10 cm in diameter.

The patient's blood is circulated through the semipermeable cellulose membrane and leaves through the tubing to the venous side of the circuit, while the rinsing or dialysing fluid circulates on the outside. (Fig. 4) Rinsing fluid also circulates crosswise the fiberglass mesh. The rinsing fluid is pumped into the bottom of the can in which the coil is firmly fitted. The fluid flows up through the screening and over the top of the container and falls back into the tank.

Polyvinyl chloride tubings and nylon connecting pieces are used in this set-up. Polyvinyl tubings have the advantage of setting properties, so that less heparin than usual is used in the system.

Blood required for priming is approximately 1500 ml. At a flow rate of 200-400 ml of blood per minute, the average urea removed in the course of six hours is 60 - 90 grams. At this rate, urea clearance is about 140 ml per minute. The pressure required to pump the blood through the dialyser at this rate is approximately 160 mm Hg. The sygmamotor pump is so designed that it maintains the dialysing fluid flow at 3 - 5 liters per minute. At this rate of flow,

PHOTOGRAPH IV

DOG UNDERGOING HAEMODIALYSIS--The dog lying on the scale is undergoing dialysis. The tank with its plastic cover is seen near the wall. Inside the inner container is the kidney coil, held in place by a metal band. Beside the tank, on the right hand side, is a sygmamotor pump and switches for thermostat circulation and drainage of the dialysing fluid. A tycos anaeroid manometer and a bottle of saline connected to side arm are held up by an intravenous pole.

the ultrafiltrate is approximately 300 ml (2-6 pounds weight loss during dialysis). The outflow pressure could be increased to 250 mm Hg in which case there will be a loss of fluid of approximately 700 ml per hour or 6-8 pounds in one hour. The blood from the dog is pumped from the femoral artery into two tubes of the arterial set. These tubes pass through the sygmamotor pump so that substantially the same amount of blood in both tubes is pumped into the kidney coil.

After traversing the 90,000 sq. cm surface of the cellulose membrane, which is constantly being inundated by circulating rinsing fluid, blood leaves the coils through the venous end of the set (the periphery). Before the blood enters back into the dog through the femoral vein, it flows through two filter chambers of the venous set, where air bubbles are trapped and blood flows can be observed. (Photograph 3)

7. PERMANENT EQUIPMENT CONSISTS OF: (Photograph 4)

1. Sygmamotor pump

2. A 100 liter tank for rinsing fluid. The tank is made of stainless steel. It has a clear plastic cover or transparent lid, so as to prevent excessive steaming. There is a platform for the sygmamotor pump, a can or container for the dialysing unit (cellulose tubing and fiberglass screen). There is also a metal board on the side of the platform, where switches for drainage of the tank, circulation of the rinsing fluid, and thermostat are found. The tank has large inflow and outflow pipes for quick changing of rinsing fluid.

8. ADDITIONAL EQUIPMENT

Some of this equipment is needed during dialysis: 8 Kelly clamps, 20cc syringe and 'tapered' cannulae especially suited for dialysis tubing connections.

9. RINSING OR DIALYSING FLUID

The rinsing tank contains 100 liters of fluid. The temperature of this tank is thermostatically controlled by an electric heater, and kept at 37° - 39°C. (100° - 102°F.)

The dialysing fluid contains sodium chloride, sodium bicarbonate, potassium chloride, calcium chloride, magnesium chloride, glucose and lactic acid in concentrations shown in Table 1.

In clinical practice, to maintain the pH at 7.4 during dialysis, 90% O_2 with CO_2 is bubbled through the rinsing fluid. This method, besides maintaining a stable pH, has the advantage of oxygenating the blood during dialysis.

10. ASSEMBLING THE DIALYSING UNIT

The coil unit is removed from the plastic bag and firmly fastened into the inside container can. A flat steel belt is slid and fastened over the top of the coil to keep it in the can during dialysis. The tubes for the inflow and outflow are found in the hollow space of the central core. The arterial tubes have clear vinyl plastic ends with cotton plugs, while the venous tubings are attached to the periphery of the coil and terminate in 'male' connectors. A yellow band is attached to corresponding inflow and outflow tubes.

TABLE 1

COMPOSITION OF DIALYSING FLUID

COMPONENTS	G/100L	Na^+	K^+	Ca	Mg^{++}	Cl^-	HCO_3^-	GLUCOSE
NaCl	585	100				100		
$NaHCO_3$	252	30					30	
KCl	22.4		3			3		
$CaCl_2$	29.4			4		4		
$MgCl_2$	15.0				3	3		200
Total in meq/l		130	3	4	3	110	30	

Lactic Acid - 20 cc to adjust pH to approximately 7.4

The cotton plugs can be either removed by a small hemostat, or part of the plastic ends can be cut off by a sharp straight scissors. The green protectors from the plug-ins (male) on the arterial side are removed. The plug-ins are inserted into the 'female' cut-ends of the inflow tubes. Kinks in the tubings should be avoided at all cost.

The venous connecting tubes are usually sealed together. They require to be cut in the centre. The green covers on the plug-ins of the outflow tubes are removed and the plug-ins similarly inserted into the outflow tubes of the coil unit.

These connections may seem confusing at first, but closer examination will show that both the inflow and outflow connections have male and female tubing connections which cannot be easily confused.

The tubing connections should be wired to make doubly sure that an air leak does not occur. A tycos anaeroid manometer is tightly fitted into one of the side arms on the filter, especially designed for measuring pressure from the coil. The other two side arms on each filter chamber are clamped with Kelly forceps. (Photograph 4)

On the venous set, there is a plastic ring, sometimes green in colour, which is used for hanging the filter chambers in an upright position, with the filter chambers at the bottom and the tycos above. Clamps are placed on the arterial inlet tubing, the venous tubing and the infusion side arm, which is connected with an intravenous tubing to a bottle of 1000 cc 5% D/Normal Saline.

The rinsing tank is filled with 100 liters of warm tap water

(37°C.) which is circulated through the screening of the coil unit for about ten minutes. This water is removed from the tank and then filled with dialysing (rinsing) fluid.

11. PREPARATION OF THE RINSING FLUID

The NaCl, $NaHCO_3$ and KCL are poured into a separate container of hot water and thoroughly mixed till the salts are completely dissolved. Meanwhile the tank is being filled with warm tap water. When the water fills the tank to about 80 liters, the taps are closed.

Two hundred grams (200gm) of sugar is poured into the dialysing fluid tank. Then $CaCl_2$ and $MgCl_2$ are mixed in their own separate bucket and completely dissolved before they can be added to the rinsing solution. After addition of 20 cc of lactic acid to the rinsing solution, the solution of $MgCl_2$ and $CaCl_2$ is added to the tank. Lactic acid, besides adjusting the pH, also prevents precipitation of calcium into the bottom of the tank. The tank is filled to 100 liter mark and the temperature kept between 37° and 39°C.

As a final check for the isotonicity of the rinsing fluid, 5 cc of arterial blood is mixed with 5 cc of the rinsing fluid and spun at 200 rev/min. for fifteen minutes. If hemolysis does not occur, the solution is isotonic and satisfactory for use. If, however, hemolysis occurs, the solution should be discarded and a fresh solution should be made up.

In clinical practice, if the object of dialysis is hyperpotassemia, then one half of the usual potassium concentration is used in the dialysing fluid. It is also important to hydrate a dehydrated

patient before dialysis is done because of considerable ultrafiltrate that is removed in one hour.

In cases where dialysis is carried out for six hours, the rinsing fluid should be changed at least once.

It is also important to note that dialysing fluid must be prepared immediately prior to dialysis to prevent $Ca^{\bullet}$ and $Mg^{\bullet}$ from precipitating upon standing. Preparation of the solution of $MgCl_2$ and $CaCl_2$ in water with the temperature above 43°C (110°F) may also lead to the precipitation of $Ca^{\bullet}$ and $Mg^{\bullet}$ ions.

12. TESTING THE KIDNEY COIL

The circulating pump is switched on and observations are made on how the dialysing fluid circulates through the screen of the coil unit. The rinsing fluid circulates upwards and crosswise through the polygrass mesh. Care is taken that no testing of the kidney is done before the coil is wet.

The pump tubes of the arterial set are placed in the sigmamotor pump, with the plastic circular stops just outside the pump housing on the inflow side of the pump. The pump tubes must be properly placed in the holes of the pump housing or else they will not function properly. The tubing should not be pinched when the sigmamotor plates are closed.

The whole set is re-examined before priming the machine with 5% D/Normal Saline. Having made sure that the unit is airtight and that all equipment to be used during dialysis is nearby, the Kelly clamps on the side arm and on the arterial inlet are released

and the solution allowed to fill the inlet tubing by gravity. The Kelly clamp is put back when the inlet tubing is filled with 5% D/Normal Saline. In filling this tube, all bubbles of air must be expelled.

A special regulating screw clamp is snugly applied on the venous side of the tubing. This clamp is essential for the regulation of ultrafiltration pressure in the coil.

The sigmamotor pump is started very slowly, observing whether the pump tubings are receiving the same pumping strength of the sigmamotor machine. Oftentimes air is trapped in the pump tubes of the arterial set. These bubbles of air are easily removed by bending the outflow ends upwards. A slight downward bend of the plastic stops also helps in the removal of air from the pump tubes.

When this is done, 100 ml of heparinized blood from a donor dog is pumped through the unit. This is followed by 5% D/Normal Saline. Leaks can be detected by the appearance of blood in the dialysing or rinsing fluid. The sigmamotor pump should always be stopped before bottles of either blood or saline are empty to avoid introducing air into the system.

If no leak is noticed, running of the sygmamotor pump is continued, gradually increasing the speed till the flow rate reaches 200-400 ml of saline per minute. At this rate, the speed control plate of the pump is clamped with a Kelly forceps. The flow rate is determined by timing how long a 500 ml bottle of 5% D/Normal Saline takes to empty into the circuit at a horizontal flow in both filter chambers.

Another method used for measuring flow rate is to collect outflow from the kidney into a graduated one liter flask. After the circuit is primed with 5% D/Normal Saline, it is again primed with 1500 cc of fresh blood.

Every dialysis requires one or two donor dogs, which are weighed, heparinized, cannulated into the femoral artery and bled into a sterile one-liter empty bottle. The blood is kept in the refrigerator until the time it is needed for priming the kidney.

When the kidney is primed with blood and there are no air bubbles anywhere in the tubes, the arterial outflow tubing is connected to the femoral artery of the dog through the tapered cannula. The venous inlet is similarly connected to the venous cannula. Meanwhile, the clamp for adjusting the flow and the ultrafiltrate pressure is adjusted to maintain a pressure of 160-180 mm Hg. The Kelly clamps on the tapered cannulae are not released until another check is done on the circuit and its connections. Then the chief operator gives the sign to his assistant (if he has one) and the two Kelly clamps are removed simultaneously with the switching on of the sygmamotor pump.

The chief operator concentrates on the proper working of the whole machine, while the assistant keeps a constant check on the vital signs of the dog. Replacement of fluid lost by the dog is determined by the amount of weight the dog loses during dialysis, the blood pressure, the turgor and elasticity of the dog's skin. Hematocrit % is also helpful in determining the amount of fluid lost by the dog during ultrafiltration.

Dialysis was carried on for the whole hour in our experiments. Once dialysis starts, it should not be stopped to avoid settling out of erythrocytes in the dialyser.

Occasionally during the priming of the kidney machine with blood, the level of blood in one filter chamber may be higher than in the other and it may obstruct vision of flow. In order to overcome this inconvenience, a release of the Kelly clamp on the side arm to bleed the air, will bring the blood to the desired level. In cases where the level of the blood column is too high in the filters, forcing 10-20 cc of air into the chamber will reduce the level.

During the whole period of dialysis, a special attempt is made to maintain a constant volume of blood in the machine and thus avoid change in the blood volume of the dog-patient. The visibility of the rinsing fluid is important so that if there is a leak in the dialysing membrane, it will be seen immediately.

As blood is forced through the 19,000 sq. cm of cellophane surface, a hydrostatis pressure difference across the membrane is created so that ultrafiltration as well as dialysis take place. The ultrafiltration pressure of 250 mm Hg is preferable on the blood side than on the rinsing fluid. The reasons being that besides its efficiency in dialysing out harmful substances into the bath, in case of a leakage, blood coming into the bath can be easily seen, whereas rinsing fluid going into the blood is difficult to see. This may lead to over hydration of the dog and since the bath is not sterile, bacteria may be

introduced into the animal (where aseptic technique is an important factor). Ultrafiltration also has the advantage of counteracting the colloid osmotic forces of blood plasma that operate in the opposite direction.

13. PRECAUTIONS DURING DIALYSIS

1. At flow rate of 200-300 ml of blood per minute, a dog can bleed to death in a few minutes, if a broken tube or leak is not noticed. This stresses the necessity for the operator to keep a constant eye on both the machine and the patient.

2. Occasionally the arterial wall may be sucked into the opening of the catheter, a vacuum created and air sucked through some weak opening into the tubes. Therefore, care is always taken to see that no vacuum is formed.

3. The wall of the vein may also be sucked into the open end of the tapered cannula and may lead to obstruction of flow and if not corrected, to the bursting of the kidney coil. Perforation of a vein with the outflow catheter may lead to enormous hematomas.

4. Temperature of rinsing fluid should be watched carefully at all times.

5. Occasionally, if the pump tubes are not properly positioned in the sygmamotor pump, a perforation may occur and thus a leak is created in the system.

6. Dialysing (rinsing) fluid must be isotonic before starting the circulating pump to prevent hemolysis of the blood in the cellulose.

14. METHOD OF DETERMINATION OF BLOOD CHEMISTRIES

A) Lactic Acid (Barker, S. B. and Summerson, N.H., 1941)

Principle--Lactic acid is converted into acetaldehyde by treatment with concentrated sulfuric acid. The acetaldehyde is determined by its colour reaction with p. hydroxydiphenyl in the present of cupric ions. The colour is read in a photoelectric colourimeter with a filter having a peak transmission at 560 mμ.

Reagents:

1. 20% $CuSO_4$ .5 H_2O (200 grs. $CuSO_4$ to 1,000 ml H_2O)
2. 4% $CuSO_4$ .5 H_2O (take 100 ml of the above 20% solution and dilute to 500 ml)
3. 11% Trichloracetic Acid
4. Conc. Sulfuric Acid
5. 1.5% p-hydroxydiphenyl in 3% NaOH

Lactate std. 5 mg% in 0.25% Benzoic Acid

Make up from 5% std. solution and dilute 1:100

Use the following way:

0.1 ml to 4.5 ml of water (total volume) 2.5mg%

0.2 ml to 4.5 ml of water (total volume) 5 mg%

0.3 ml to 4.5 ml of water (total volume) 7.5mg%

0.4 ml to 4.5 ml of water (total volume) 10 mg%

0.5 ml to 4.5 ml of water (total volume) 12.5mg%

To prepare 5% lactic acid std. solution

If Lithium Lactate is used: Lithium Lactate M.W. = 96.012 gr

Lactate = 89.072 gr. per mole.

To prepare a solution containing 5 gr. of lactate in 100 ml, or 5 gr.% solution with regard to lactate

$x = 5 \times 96.012 = 5.39$ gr/liter, or 89.072

Weigh out 0.539 gr. of Li lactate and dissolve it in 0.25% Benzoic Acid and make up to100 ml in vol. flask.

Working standard (5 mg%)

Take 1 ml of the above standard solution and dilute to 100 ml with 0.25% Benzoic Acid.

Procedure in the Determination of Lactic Acid

1. Treatment of the protein free sample by copper sulfate calcium hydroxide procedure of Van Slyke to remove interfering materials, such as glucose.
2. Conversion of the lactic acid to acetaldehyde by controlled oxidation with sulfuric acid.
3. Colour development by treatment in concentrated acid solution with p. hydroxydiphenyl in the presence of added cupric ions, which enhance the colour development.

Reagents:

1. 11% Trichloracetic Acid. This should be freshly prepared every two weeks and stored in the refrigerator.
2. 20% Copper Sulfate Solution ($CuSO_4 \cdot 5 H_2O$)

3. Calcium Hydroxide (CaOH)
4. Concentrated Sulfuric Acid - Reagent Grade s.g.1.84
5. 4% Copper Sulfate Solution
6. 1.5% p. hydnoxydiphenyl in 3% Sodium Hydroxyde (NaOH)
7. Lactate Standard - 5 mg% Keep in refrigerator in 0.25% of Benzoic Acid.

Caution:

This method is extremely sensitive. Since all cells produce lactic acid, there is enough on the fingers to destroy the accuracy of the test. Therefore, it is advisable not to mix tubes by inverting with the centrifuge tube or touching the tips of the pipettes.

Method:

Take 2 cc of whole blood and add dropwise to 8cc of cold 11% T.C.A. Cover with paraffin paper, shake and centrifuge for five minutes. The supernatant fluid is stored in the deep freeze.

1. Place 1 cc of supernatant fluid in a centrifuge tube.
2. Add 3.5 cc of distilled water
3. Add 0.5 cc of 20% copper sulfate solution.
4. Add approximately 0.5 g calcium hydroxide (a little on the end of a spatula). Cover with paraffin paper and shake well. The solution in the tube should turn bright blue and if it is pale, add more calcium hydroxide.
5. A blank tube, containing water in place of supernatant, and a standard should be set up similarly.
6. Stand for at least thirty minutes, shaking occasionally and then centrifuge for thirty minutes.

7. A 1 cc aliquot of the supernatant is layered carefully on 6 cc of conc. sulfuric acid in a pyrex tube in an ice bath. Aliquots should be taken in duplicate.
8. Shake tubes quickly to mix under ice water. Localized heating due to uneven mixing will cause the oxidation of acetaldehyde to acetic acid.
9. Heat the tubes for five minutes in boiling water.
10. Cool to 30° C and add one drop of 4% copper sulfate solution. To this is added 0.1 cc diphenyl reagent. A white precipitate will form.
11. Mix carefully and stand at 28-30°C for thirty minutes with occasional shaking.
12. Heat in boiling water bath for ninety seconds.
13. Cool, transfer to colourimeter tubes, and read percent transmission on Coleman Junior at wavelength 560.

Standard Curve

0.0, 0.1, 0.2, 0.4, 0.6 cc lactate standard (5mg%) is pipetted into centrifuge tubes and water is added to make the volume up to 4.5 cc. Proceed as above in stages. These amounts correspond to 0.0, 2.5mg%, 5mg% and 15mg% lactate in whole blood and a straight line is obtained if the percent transmission is plotted versus concentration in mg% on semi-log paper.

B) pCO_2, pH and HCO_3 Determination

Principle in the determination of blood chemistries (Guyton, 1961), (Wright, 1961), (Davenport, 1961)--The Astrup (1955, 1956, 1957, 1958) method is one of the best and quickest methods available in the quick analysis of any acid-balance in the blood.

When blood comes in contact with carbon dioxide of specific partial pressure, it will take up or give off CO_2 until a state of equilibrium is reached. It was Peters and Van Slyke (1932) who first worked on the absorption curve for carbon dioxide in the blood.

Increase of partial pressure of carbon dioxide leads to a concomittant increase in the absorption of carbon dioxide and vice versa - CO_2 will be expelled if there is decrease in partial pressure.

Blood will take up CO_2 in the capillaries where the partial pressure is low under normal circumstances. The importance of this function of the blood cannot be overestimated.

Henry's law states "The content of gas physically dissolved in a liquid is proportional to the partial pressure of the gas above the liquid." This same law applies to blood and plasma with regard to CO_2. Changes brought about by chemical means are of more importance than the actual physical absorption or separation of CO_2.

The ability of the hydroxyl ion to combine with CO_2 to form a bicarbonate or vice versa is the most important chemical reaction in the

process of CO_2 exchange in the blood.

$$OH^- \uparrow CO_2 \qquad HCO_3$$

In accordance with the law of mass action, the relation between the concentrations of the components involved in this scheme is given by the following equation:

$$C_{OH} \, C_{CO_2} = K \cdot C_{HCO3}^-$$

Looking at this equation, it is evident that

1. An increase in CO_2 partial pressure or higher CO_2 partial pressure must also lead to an increase of HCO_3. In order to produce HCO_3, OH^- is also required and thus leads to the decrease of C_{OH^-}.

2. Similarly, a decrease of CO_2 (lower partial pressure) leads to a decrease in HCO_3^-; but when HCO_3^- dissociates, OH^- is produced and hence OH^- concentration will rise correspondingly.

3. This decrease of OH^- brought about by an increase of CO_2 is counteracted by the addition of OH^- ions, the ability of converting CO_2 into HCO_3^- will be improved correspondingly.

4. Knowing the concentration of OH^- ions and the partial pressure of CO_2, the concentration of HCO_3^- ions can be calculated.

Since the pH of an aqueous solution is specific also for the concentration of OH^-, according to the temperature, it is sufficient to know the pH of the blood sample and the partial pressure of CO_2 to be able to calculate the concentration of bicarbonate.

According to the Astrup Method, the partial pressure of CO_2 can only be determined indirectly. Astrup's Method allows the sample to equilibrate with a gas mixture whose CO_2 partial pressure has been predetermined. When the equilibrium is attained, the pH is determined

and then bicarbonate content is calculated under the conditions given below.

The plasma relationship between pH, $C_{HCO_3^-}$ and C_{CO_2} are covered by the Henderson-Hasselbalch equation:

$$pH = g.110 + \log \frac{(HCO_3^-)}{(CO_2 + H_2CO_3)}$$

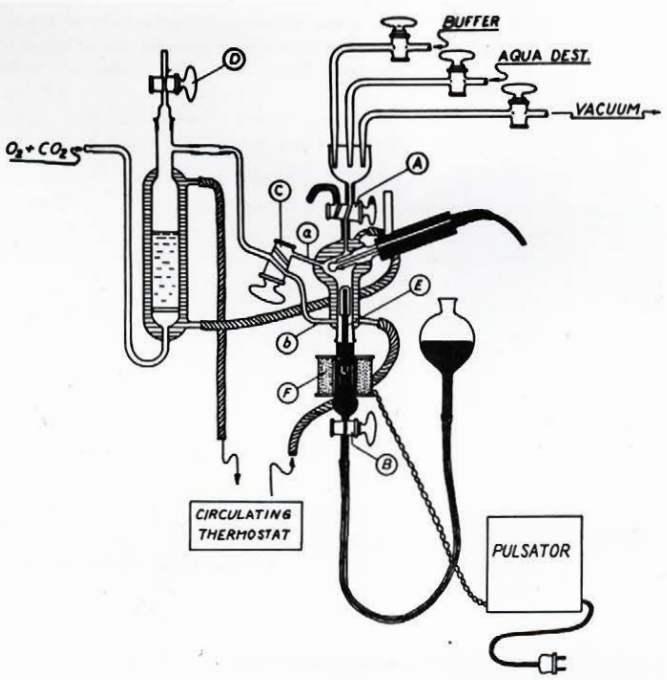
$$pH - 6.110 - \log \frac{(HCO_3^-)}{pCO_2 . 0.03}$$

In this equation, (HCO_3^-) means the bicarbonate concentration in millimols per liter and pCO_2 is the partial pressure of CO_2 in mm Hg.

The bicarbonate concentration at a pCO_2 of 40 mm Hg is called 'standard bicarbonate'. The standard bicarbonate then "Is the concentration of bicarbonate in the plasma, which is separated from the cells with the hemoglobin completely oxygenated, at a pCO_2 of 40 mm Hg and at a temperature of 38° C." (Astrup, 1958). The normal 'standard bicarbonate' in humans is 23± 2 meq/l. In dogs it ranges between 17-25 meq/l.

Astrup has achieved to establish the correlation between pCO_2 and pH for plasma at varying composition. A resulting set of curves, serves the purpose of finding the actual pCO_2 of blood at the moment of sampling.

The Van Slyke method of volumetric and manometric determination of total CO_2 is usually not followed by a pH determination, which is an important omission. The Astrup Method has bridged this important gap.



Arrangement for equilibrating plasma with gas mixtures of known compositions. For detailed explanation see text.

Fig. 5.--THE ASTRUP APPARATUS

Astrup Procedure

a) Apparatus

The Astrup apparatus (Fig. 5) consists of a chamber with two sides, one at the top, A, and the other at the bottom, b. A two way stop-cock, C, connects both side tubes with a moistening chamber, which contains distilled water enveloped by a water jacket kept at 38°C. A mixture of O_2 and CO_2 passing the moistening chamber is saturated with water vapor at the temperature of the water in the water jacket. From moistening the chamber, the gas mixture can be led to the electrode chamber through one of the side tubes and/or it can be allowed to escape through cock D, when two way cock C is closed. The chamber is provided with an agitator, E, operated by a coil, F, which is fed from a pulsator. The agitator moves up and down at a frequency of about three cycles per second. The downward movement is brought about by the attraction of the coil and the upward movement by the buoyancy.

A circulating thermostat (Photograph 5) and a pH meter are placed on either side of the Astrup apparatus. A cylinder of 10% CO_2 is kept in a horizontal position to "avoid decrease in the CO_2 concentration of the outflowing gas during use as the higher specific gravity of CO_2 relative to O_2 causes the CO_2 concentration in the lower part of the cylinder to decrease when standing upright." (Astrup, 1957)

b) Standard Buffer Solution

This solution is used for adjustment of the pH meter. The preparation consists of an M/15 phosphate, prepared from 200 M/15 primary

PHOTOGRAPH V

THE ASTRUP APPARATUS--This is the Astrup apparatus described in Fig. 4. The pH meter can be seen on the right hand side of the picture, close to the apparatus and the circulating thermostat is similarly situated on the left hand side of the apparatus.

potassium phosphate (9.078g dry KH_2PO_4 p.a. (Merck) dissolved in one liter of redistilled water) and 800 ml M/15 secondary sodium phosphate (11.8667 g Na_2HPO_4, $2H_2O$ p.a. (Merck) dissolved in one liter of redistilled water). The pH of this solution is taken to be 7.360 at 38°C. The buffer is best stored in a pyrex bottle provided with a sodalime tube.

c) Prodadure

It is beyond the scope of this brief description to go into the details of the Astrup procedure.

Arterial blood is anaerobically collected into a 20 cc syringe as described above. Half the sample is centrifuged under liquid paraffin. Equilibration of the plasma with O_2-CO_2 mixture is made. The gas mixture enters the measuring chamber through the upper side tube (a) and escapes through cock A. By means of the mercury, the plasma level is lowered so that the agitator is above the surface of the plasma each time it reaches its top position and a fresh film of plasma continuously comes into contact with the gas. The equilibration generally takes six to ten minutes. When this has been completed, cock C is closed and the plasma level is elevated to surround the electrode. The pH is then measured after two minutes.

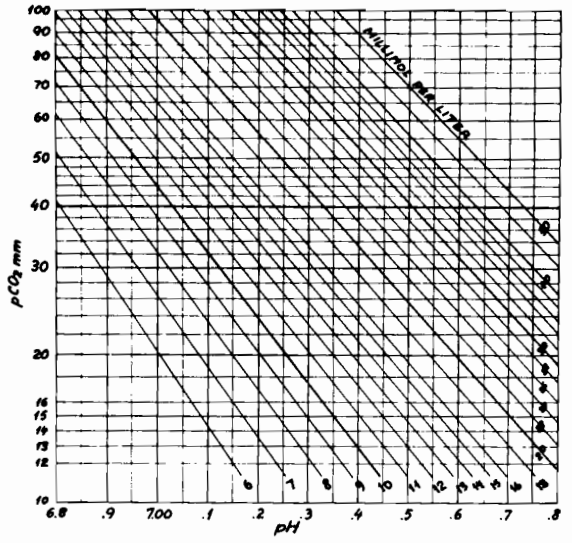
The pCO_2 in aqueous solution is calculated from the carbon dioxide concentration, measured as follows:

$$pCO_2 = \frac{(B-W \times \text{percent } CO_2}{100}$$

B = Barometric pressure in mm Hg

W = Vapour pressure of water at 38° C (= 50 mm Hg)

After the anaerobic introduction of the sample in the electrode chamber, the actual pH is measured. Then the plasma is equilibrated



Relation between pH and pCO_2 at bicarbonate concentrations in plasma of normal protein concentration. The figures at the lines signify bicarbonate concentrations measured in mMol/L.

Fig. 6

with an O_2-CO_2 mixture of known pCO_2 of approximately 40 mm Hg, the pH is measured again and the position of the pH-pCO_2 curve is found by using the diagram on Figure 6.

Finally, the pCO_2 is determined by means of the curve and the actual pH. Knowing the actual pCO_2 and the actual pH of the plasma sample, the total content of CO_2 can be calculated by means of the Henderson-Hasselbalch equation:

$$pH = pK_1 + \log \frac{(HCO_3)}{(CO_2 + H_2CO_3)}$$

The actual bicarbonate concentration expressed in mM/l can be calculated by inserting in this equation the pH value measured at 38°C, taking pK_1 to be 6.110 and replacing (pCO_2 + H_2CO_3) expressed in mM/l, by pCO_2 in mm Hg multiplied by 0.03. In short, the bicarbonate concentration and that of the physically dissolved CO_2 gives the total CO_2.

15. METHOD OF DETERMINATION OF SERUM ELECTROLYTES

A. Materials Used:

2 ml pipette, 100 ml volumetric flask, double distilled water, oxygen tank, propane tank and galvanometer scale. (Photograph 6)

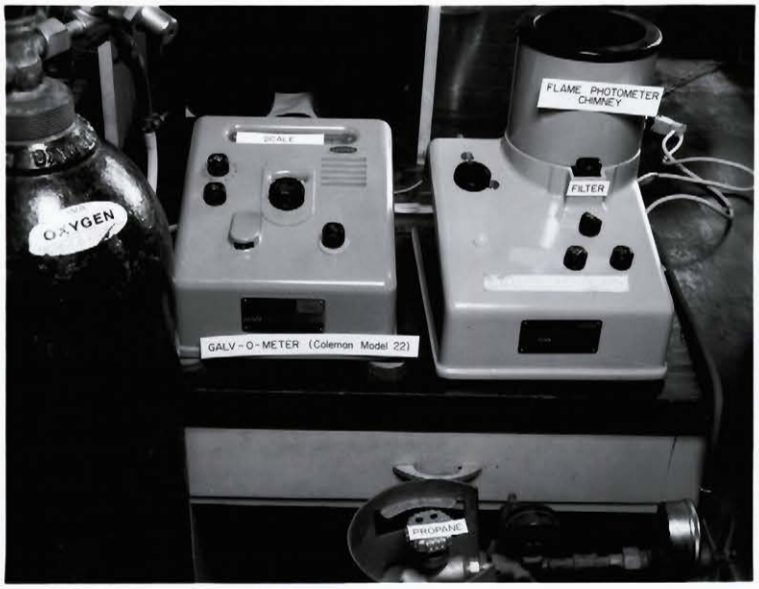
B. Method

1. Sodium--The method used for serum Na^+ estimation in our experiments is based on the original method adopted by Barnes: (Valley, 1962)

a) Pipette 0.5 ml of serum or plasma into a 100 ml volumetric flask.

b) Fill the flask with water to within 5 ml of the

PHOTOGRAPH VI



COLEMAN MODEL 22 FLAME PHOTOMETER.--This is used for determination of serum potassium and sodium. The propane tank is seen at the bottom of the photometer chimney and filter. The oxygen tank is on the left side of the photometer, while the reading scale is at the very top of the machine.

mark and then add 2 ml of 1% Sterox S.E. to make up to the volume with water.

c) Adjust machine with oxygen at 10.5 lbs. and propane at 5 lbs.

d) Set blank back to zero and stronger working standard at 150 meq/l on the galvanometer scale.

e) When the machine is stable, read the sample of serum directly from the scale.

f) When working, a beaker of the blank solution should be kept separate and used only for flushing through the atomizer.

Principle--In the excitation of electrones, each absorbs energy and releases it in light of specific wave length and the amount of light emitted is measured by photoelectric tubes.

Reagents

a) 1% Sterox S. E. in water

b) Na^+ Standard 0.75 meq/l Na^+ and 0.02% Sterox S.E. -- equivalent of 150 meq/l Na^+ in diluted serum or plasma.

c) 0.5 meq/l Na^+ and 0.02% Sterox S.E. -- equivalent of meq/l Na^+ in diluted serum or plasma.

d) Blank and cleaning reagent 0.02% Sterox S.E.

Caution--All reagents mentioned in Na^+ and K^+ techniques should be stored in pyrex or polythene bottles. Whenever water is mentioned, double distilled water is meant.

2. Potassium

a) Pipette 0.5 ml of serum or plasma into a 25 ml volumetric flask. Fill to within 10 ml of mark with water.

b) Pipette 5 ml of reagent 2 into the flask and make up the volume with water.

c) Adjust the flame photometer with 10.5 lbs. of O_2 and 5 lbs. of propane.

d) Set reagent 3 to zero and reagent 1 to 5 meq/l on the scale when the machine is stable.

e) Read the sample of serum or plasma directly from the scale. Between each reading of serum or plasma, flush the atomizer with reagent 4.

Reagents

a) K^+ Standard - 0.1 meq/l potassium, 25 meq/l sodium and 0.02% Sterox S.E.

b) 125 meq/l Sodium and 0.1% Sterox S.E.

c) Blank: 25 meq/l sodium and 0.02% Sterox S.E.

d) Cleaning reagent: 0.02% Sterox S.E.

3. Chloride

Method and Materials--This method is based on Folin-Wu:

a) To 0.2 ml of plasma add 1.8 ml of water.

b) Add 0.06 ml of the indicator and titrate with the mercuric nitrate with a microburette calibrated to 0.01 ml. One

ml should equal 100 drops. When filtration is done directly on plasma, the colour at first is salmon-red, changing to deep violet when the titration is begun, then becoming pale yellow or colourless. A sharp change to pale violet then, denotes the end point.

c) Carry out the titration on 2 ml of the standard chloride solution.

Principle--Plasma is titrated with a mercuric nitrate solution, using diphenylcarbazone as indicator, which gives a violet - blue complex with mercuric ions.

Mercuric chloride is formed and remains in solution, but it is so very slightly dissociated that sufficient mercuric ions to give this colour are only present when all the chloride is titrated and excess mercuric nitrate is added.

Reagents

a) Mercuric Nitrate solution, made by dissolving 3 grams of mercuric nitrate in a few hundred milliliters of water. The 20 ml of 2N. nitric acid is added to make up a litre of water. It is important to adhere to this formula strictly, otherwise the end point will not be sharp.

b) Diphenylcarbazone indicator. Dissolve 100 mg in 100 ml of 95% alcohol. Keep this solution in the dark in a refrigerator.

c) Standard chloride solution. Dissolve 585 mg NaCl, dried at 120°C in water and make up to one liter.

16. EXTRACTION AND BIOASSAY OF HISTAMINE

Principle

Guinea pig ileum is particularly sensitive to histamine and hence the contraction obtained and recorded on a rotating drum can be used for bioassay of unknown quantity of histamine in any extracts.

Procedure

The 'Bioassay Method' of C.F. Code (1956 Mayo Clinic) was used in our experiments.

1. Blood samples of 10 cc were taken at intervals of 2 secs., 10 secs., 30 secs., 1 minute, 2 minutes, 5 minutes, 10 minutes 1 hour, 2 hours, and 2½ hours.
2. The blood or a piece of tissue is weighed accurately on a balance.
3. Add 10 cc of 10% T.C.A. (Trichloroacetic Acid) and homogenize and centrifuge at 3,000 r.p.m. for fifteen minutes.
4. Take the supernatant fluid and pour it in a flask.
5. To the residue, add 5 cc of 5% T.C.A., mix and then centrifuge at 3,000 r.p.m. for fifteen minutes.
6. Pool with the first supernatant.
7. Extract, using air reflux and heat for 1½ hours. Extraction should be in flash evaporator using absolute alcohol 3x under pressure. The end product should be absolutely dry.
8. Dissolve in 10 cc tyroden solution and do the bioassay, using guinea pig's ileum and organ bath.

17. EXPERIMENTAL PROCEDURES ON DIFFERENT GROUPS OF DOGS

GROUP I: DIALYSIS OF NORMAL DOGS

a) Without Prophylactic Antibiotics--Five dogs were dialysed for one hour. After the completion of dialysis, the dogs' incisions were closed up with number I merselene sutures and taken to the recovery room. No prophylactic antibiotics were administered. Vital signs were recorded in the manner described above.

b) With Prophylactic Antibiotics--The five dogs in this group, after the end of the experiment were given 2 cc of Fortimycin intramuscularly. This was the only variable between these two groups of dogs.

GROUP II: ENDOTOXIN SHOCK

a) Endotoxin shock and early dialysis with old and new coils--Twenty-eight dogs were used in this group, fourteen experimental and fourteen controls. All the twenty-eight dogs were subjected to the same experimental procedure described above. Both groups of dogs received 3 mg/kg of endotoxin intravenously. In addition to the recording of vital signs, blood samples for chemistries, electrolytes and hematocrits were collected in ten experimental and ten control dogs. Dialysis was begun thirty to thirty-five minutes after the injection of endotoxin. No form of treatment was given to the control dogs. At the end of the experiment, prophylactic antibiotics, 2 cc of Fortimycin, was administered intramuscularly before the dogs were taken back to their cages.

b) Endotoxin Shock and Early Dialysis with New Coils Only--Ten dogs were used in this study. These dogs were dialysed thirty to thirty-five minutes after endotoxin administration. The important variable in this group, when compared with the above early dialysis, was the use of new coils only.

c) Endotoxin Shock and Late Dialysis with New and Old Coils--Fifteen dogs were employed in this group. The only difference between this group and the early dialysis is that, instead of dialysing these dogs thirty to thirty-five minutes after endotoxin injection, they were dialysed in three and a half to four hours after the administration of endotoxin. Electrolytes, chemistries and hematocrits were not determined.

d) Endotoxin Shock and Histamine--Six dogs were used in this group. After the usual infrainguinal ligament incision was made, and the femoral artery and veins well exposed, a polyethylene tube, 4 cm in diameter, was inserted into one of the femoral arteries. The catheter was pushed so high that its proximal tip was one inch above diaphragm. Specimens for whole blood and plasma histamine were taken at two seconds, ten seconds, thirty seconds, one minute, two minutes, one hour, two hours, and two and one half hours.

Plasma histamine levels were determined in one group of three dogs, while blood histamine levels were determined in the other three dogs.

For the extraction of histamine from these samples, the bioassay method of C.F. Code described above was used.

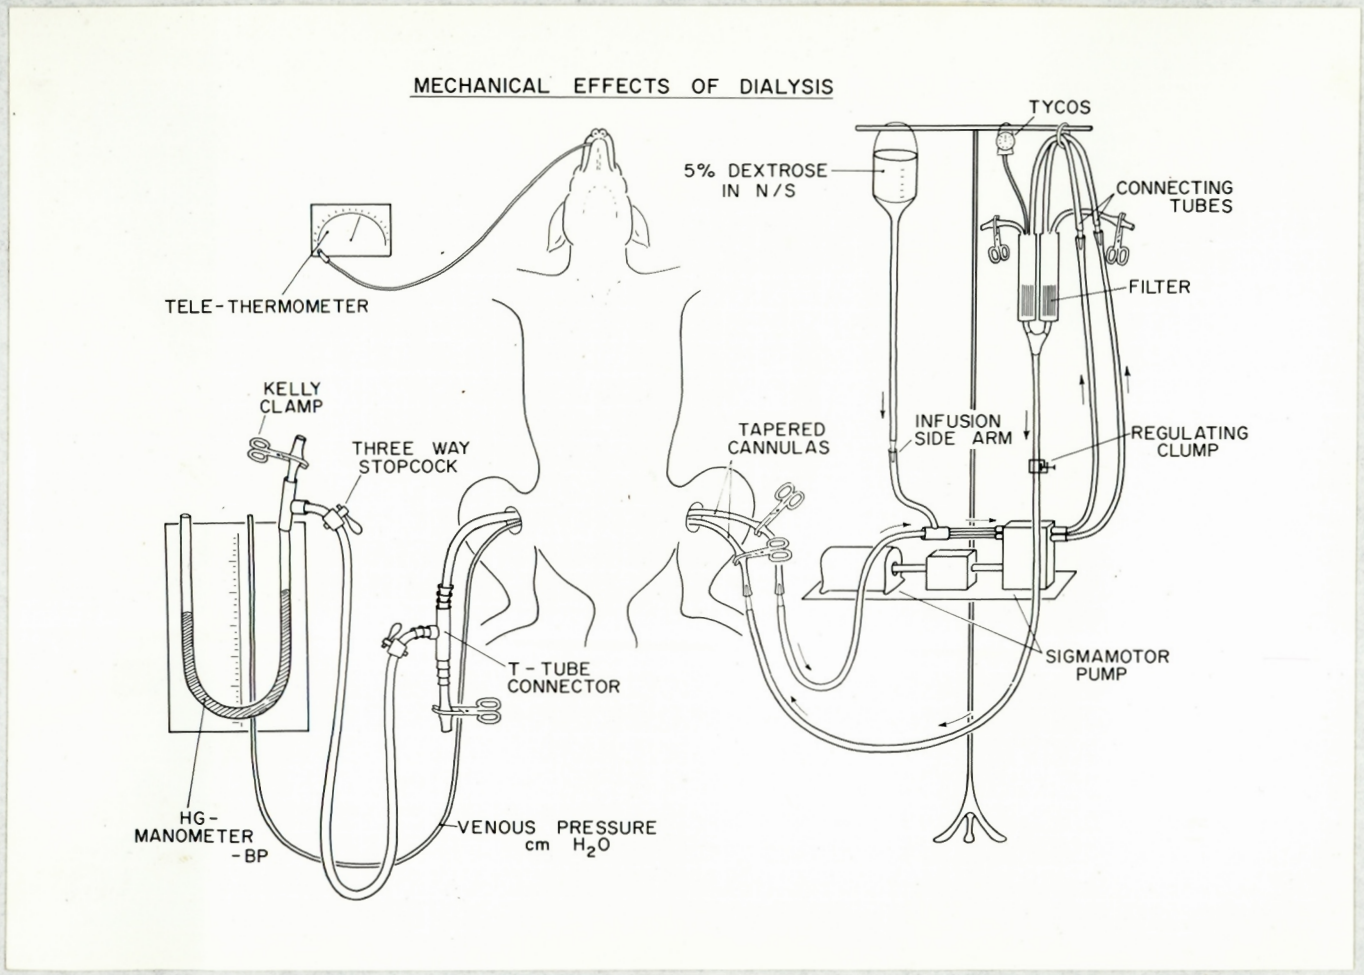


Fig. 7.--This diagram illustrates the set up of the apparatus used in 'Mechanical Effects of Dialysis'. It is noted that this set up is for all intents and purposes the same as Fig. 3 (Dialysis), except that in the former, the bath, the kidney coil and the dialysing fluid are absent - an important omission.

e) Endotoxin shock and Mechanical Effects of Dialysis--(Fig. 7) Ten dogs were employed in this group. The important difference between this group and the early and late dialysis groups is the absence of the kidney coil and the rinsing solution. This group is an important double control for the mechanical effects of dialysis during haemorrhagic and endotoxin shock. This is in effect an extracorporeal circulating system of hemodialysis. (Photograph 7)

The resistance to circulation was kept at a pressure of 100 mm Hg. Circulation was maintained for one hour. The weights of five dogs were continuously watched during the process of pumping. Blood chemistries, electrolytes and hematocrits were determined in five dogs.

f) Endotoxin, Morphine and Early Dialysis with Both New and Old Coils--This is the only group which did not receive nembutal. Ten dogs, five control and five experimental, were employed. Three milligrams per kilogram of body weight of morphine sulfate and .3 mg/kg of atropine were given intramuscularly one half hour before the endotoxin was administered intravenously. Samples for blood chemistries and electrolytes were not collected.

GROUP III: HAEMORRHAGIC SHOCK

a) Haemorrhagic Shock and Early Dialysis--There were ten experimental and ten control dogs used in this group. In order to shock the dogs, the modified Wiggers-Fine Technique was employed. Blood

PHOTOGRAPH VII

MECHANICAL EFFECTS OF DIALYSIS--This dog has been given .5 mg/kg Endotoxin and is undergoing 'Mechanical Effects of Dialysis'. The absence of the tank and its contents is noted, otherwise the rest of the connections are similar to the set up of dialysis.

chemistries, electrolytes, hematocrits and vital signs were determined in all the twenty dogs.

At the end of two and one half hours of shock, the blood was reinfused intraarterially into the dog by means of a syringe. Dialysis was begun soon after all the blood was back into the dog. Blood samples taken during dialysis were drawn through the three-way stopcock.

In five dogs, a polyethylene tubing 4 cm in diameter was pushed into the right auricle through the ipsilateral external jugular vein. Central venous pressures in centimeters of water were recorded simultaneously with inferior vena cava pressures.

b) Haemorrhagic Shock and Dibenzyline--The same method, Wiggers-Fine Technique, was used to bring this group of dogs into shock. There were twenty dogs in this series, ten experimental and ten control. It is to be noted that the latter group of dogs resembles the control group of haemorrhagic shock and dialysis.

The ten experimental dogs received .5 mg/kg of dibenzyline in 100 cc of normal saline intravenously after all the control parameters had been taken. One hour after the administration of dibenzyline, a second blood specimen for biochemistries and electrolytes was drawn. The dogs were then shocked for two and one half hours.

GROUP IV: DETERMINATION OF NORMAL ARTERIAL CHEMISTRIES

Five calm and docile dogs without any anesthesia were tied onto the operating table. All the dogs did not put up a struggle, since

since they had been hand picked on the basis of their tameness. By means of an 18 gauge needle, arterial blood samples for chemistries were drawn from the femoral artery. Compression was applied to the artery after withdrawal of the needle and the dog was sent back to the cage.

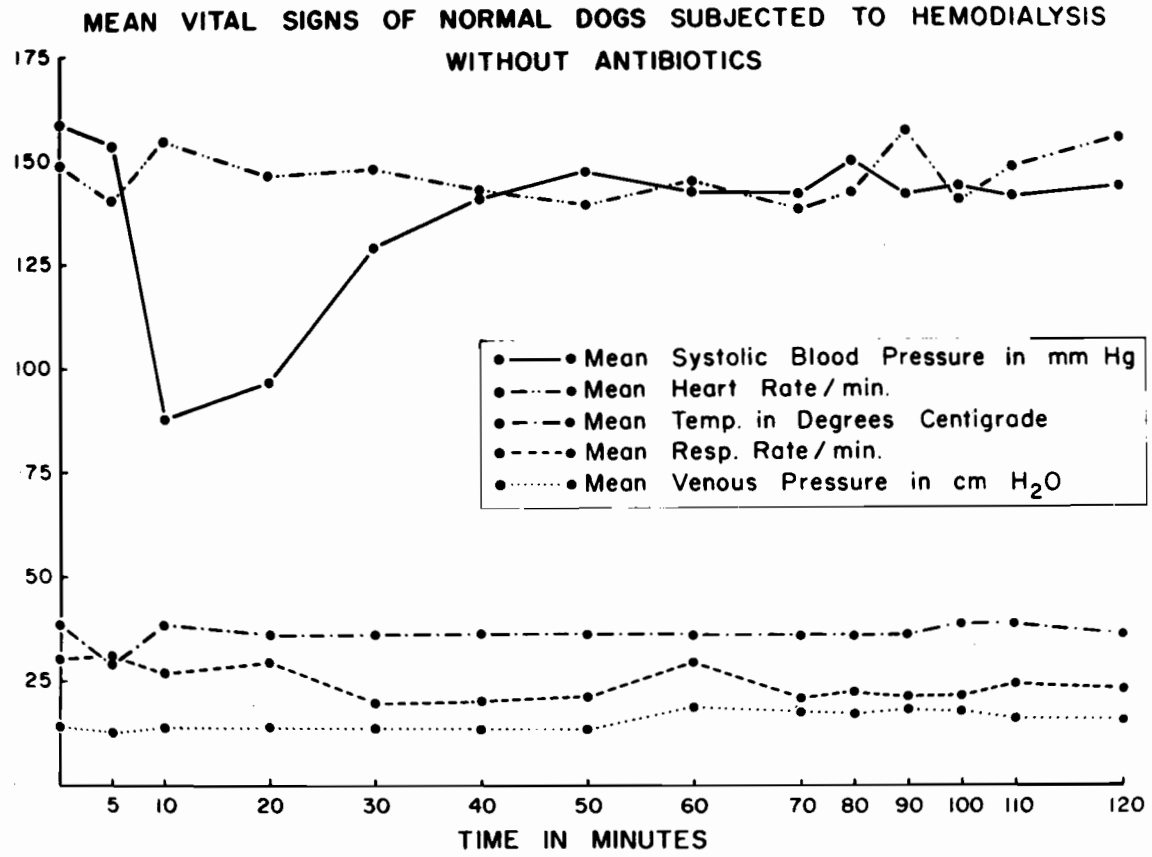

Fig. 8.--There is an initial drop in mean blood pressure, heart rate, temperature, respiratory rate and venous pressure during the first ten minutes of dialysis. Then for the next thirty minutes, all the parameters show a tendency to go back to normal levels and to stay stable till the end of dialysis.

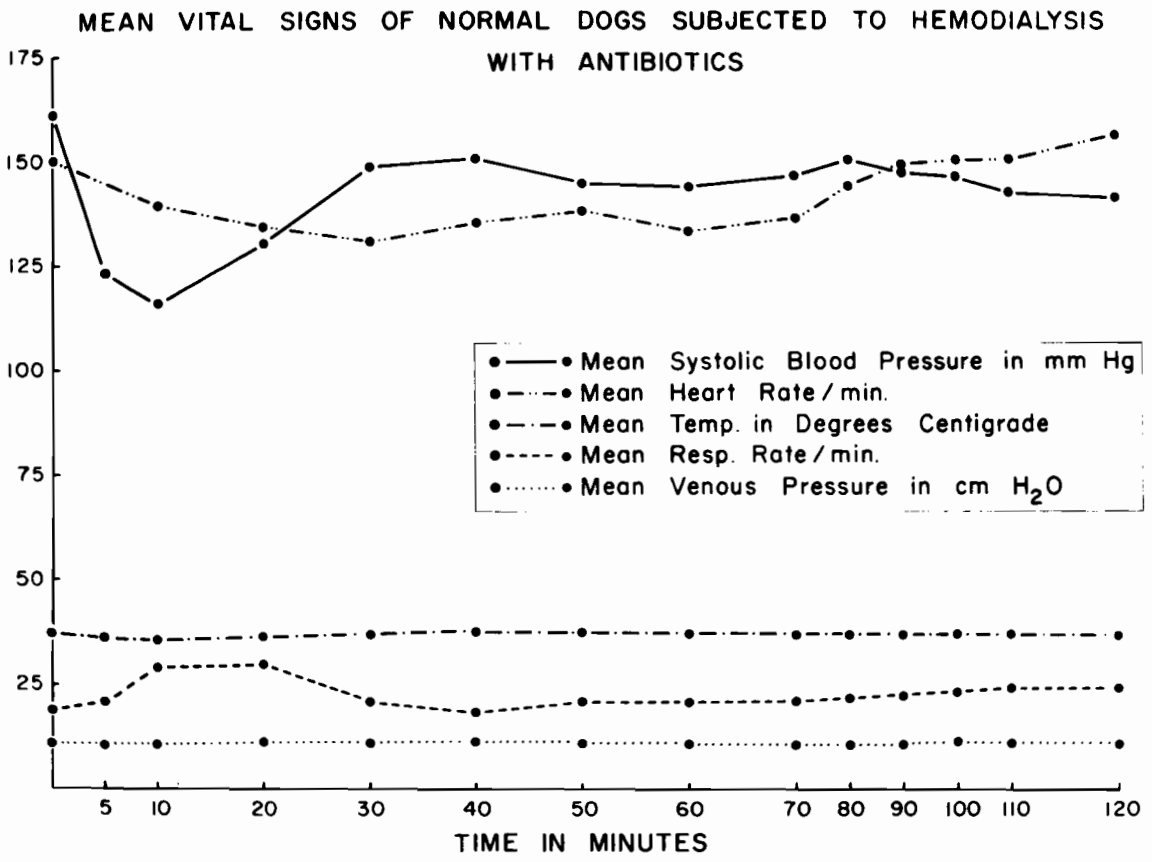

Fig. 9.--Except for the mean venous pressure and respiratory rate, the vital signs display the same tendencies observed in Fig. 8. The mean venous pressure in this group remained at practically the same level during the period of dialysis.

CHAPTER IV

RESULTS

GROUP 1:

A: DIALYSIS OF A NORMAL DOG WITH AND WITHOUT PROPHYLACTIC ANTIBIOTICS

1. EFFECTS OF DIALYSIS ON THE VITAL SIGNS OF A NORMAL DOG

a) Temperature--The mean normal temperature in a healthy dog lies between 36 - 37°C. In both groups of dogs there was a slight drop in temperature of an average 1.5°C at the beginning of dialysis. However, as a whole, after this initial drop, the temperature leveled off again till the end of the experiment. (Fig. 8 and Fig. 9)

b) Blood Pressure--There was usually a drop in systolic blood pressure, sometimes to levels as low as 50 mm Hg. Only one dog in the antibiotic group did not experience this period of hypotension. This same dog lived for five days. This phenomenon of initial hypotension following the beginning of dialysis was a common feature encountered in both groups.

c) Heart Rate--The average normal heart rate in a dog is 140 beats per minute. In both groups the values did not differ markedly and the heart rate seemed to remain at practically the same level throughout the experiment. There was a tendency towards tachycardia

during the last forty-five minutes of the experimental period.

d) Venous Pressure--The mean normal venous pressure of a dog is 6 - 6.5 cm of H_2O. The antibiotic group showed stable mean venous pressures, which remained at about 10 cm H_2O during the whole period of dialysis. The non antibiotic group showed higher mean venous pressures averaging 14 cm H_2O throughout the experimental period. The stability of venous pressures at some point during dialysis was noted in both groups. (Table 2)

e) Respiratory Rate--There was a tendency towards hypernea at the beginning of the experiment in the control dogs. During the later thirty minutes of the experiment, the respiratory rate returned to normal. The prophylactic group showed normal mean respiratory rates throughout the observation period.

At some point during dialysis, all the parameters were noted to be stable and to remain stable for a period of fifteen to thirty minutes. (Table 2) The temperature, blood pressure, heart rate, venous pressure and respiratory rate remained practically unchanged during this period. (Figs. 8 and 9) The time at which this physiological equilibrium occurred was different in each animal. (Appendices I and II)

There were no permanent survivors in the dogs that did not receive prophylactic antibiotics, while in the antibiotic group, four out of five dogs survived permanently. These survivors were subsequently used as donors in later experiments on hemodialysis.

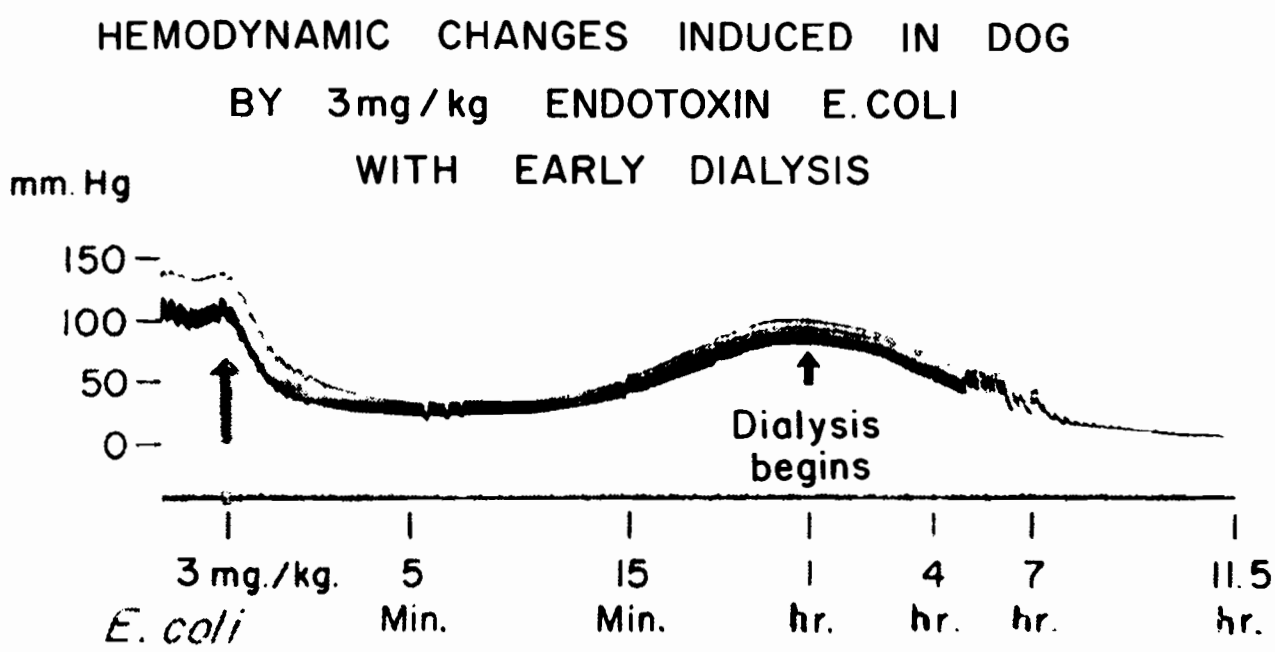

Fig. 10.--Administration of endotoxin is followed by a dramatic fall in blood pressure, which lasts for a period of thirty to sixty minutes. Then the blood pressure rises again to control levels and stays for another period of thirty to sixty minutes, after which it declines progressively till the death of the animal. The period of initial hypotension is sometimes accompanied by a marked bradycardia.

D = Dialysed Group M = Mechanical Effects

GROUP II:

B: ENDOTOXIN SHOCK

2: EFFECTS OF ENDOTOXIN AND DIALYSIS ON VITAL SIGNS
(Tables 3, 7, 8, 9, 10, 11)

a) Temperature--In all the dogs that received 3 mg/kg of endotoxin, both dialysed and control, there was a marked and progressive fall in temperatures. The difference between the control temperature and that at the end of the experiment was sometimes 5° Centigrade. High mean temperatures were noted in the group of dogs subjected to endotoxin and delayed dialysis. There does not seem to be a definite correlation between progressive drop in temperature and survival. (Appendices III, V, VII, VIII)

b) Blood Pressure--There is also a general tendency for blood pressure to fall progressively as the dog goes into shock. Immediately after administration of endotoxin, there is a dramatic fall in blood pressure to levels sometimes as low as 60 mm Hg. This period may last for thirty-five minutes to one hour. (Fig. 10) Out of seventy-nine dogs that received endotoxin, forty manifested this dramatic phenomenon of endotoxin hypotension. Three dogs never recovered from this crucial period as they went downhill and died in 3½ hours.

The control dogs in the endotoxin series showed a general tendency of maintaining their blood pressure below 100 mg Hg till the end of the experimental period. The experimental dogs and three

dogs in the-mechanical-effects-of-dialysis group generally showed a gradual rise in pressure during the last hour of the experiment. (Appendix XII) There is some correlation between survival rate and the behaviour of blood pressure during the shock period. Animals which tended to keep their mean blood pressures above 100 mm Hg during the experimental period, survived longer than those dogs which remained severely hypotensive (65 mm Hg) for over 3½ hours. All the morphine endotoxin dogs which survived permanently maintained their blood pressures well above 100 mm Hg throughout the experiment. (Table 13). One morphine-endotoxin dog which had remained hypotensive for one hour compensated at the end and it survived permanently. (Appendix XV) Dogs undergoing dialysis also showed initial drop in blood pressure at the beginning of dialysis, as observed previously in normal dogs. However, usually the dialysed dogs showed blood pressure increase at the end of the experiment, especially permanent survivors.

c) Heart Rate--(Appendices II, III, V, VII, VIII, IX, X, XI, XII, XIII, XV) In all the endotoxin dogs there was a tendency towards tachycardia after 2½ hours in shock. (Tables 3, 7, 8, 9) some groups, notably the endotoxin—mechanical-effects-of-dialysis animals, the mean heart rate was as high as 244 beats per minute. (Table 10) Five to ten minutes after the injection of endotoxin, some dogs showed a marked bradycardia to values as low as eighty beats per minute. Thirty-seven endotoxin dogs out of a total of

seventy-nine exhibited this period of bradycardia. It was of interest to notice that this period usually coincided with the period of initial hypotension mentioned above. Early dialysis was usually commenced when both bradycardia and hypotension phases had passed. (Fig. 10)

d) Venous Pressure--There was a tendency to elevation of venous pressure to averages of 8.5 cm water at the beginning of the experiment. Examining the values of individual animals, it is noted that some dogs showed initial venous pressures of 5-6 cm water. Towards the end of experimental period, most survivors maintained a venous pressure of 5-6 cm H_2O. The dogs that died during the experimental period showed a terminal elevation of venous pressure to levels as high as 13 cm water. Some permanent survivors also manifested this terminal increase in venous pressures to values as high as 14 cm water.

e) Respiratory Rate--There was a tendency towards hyperpnoea in most dogs at the beginning of the experiment, as observed in the other groups of dogs. Hyperpnoea was aggravated by endotoxin administration. The mean respiratory rate tended to rise slightly in the middle of the experiment, but in the majority of cases the rate showed little variation until towards the end of our observations. Examination of individual respiratory rates shows that permanent survivors tend to compensate well by maintaining a normal respiratory rate (18-27) towards the end.

GROUP III:

C: HAEMORRHAGIC SHOCK

3: EFFECTS OF HAEMORRHAGIC SHOCK, DIALYSIS AND DIBENZYLINE ON VITAL SIGNS (Tables XIV, XVI)

a) Temperature--(Appendices XVI, XVII, XX) The same tendency of gradual temperature depression seen in the endotoxin group was also noted in the haemorrhagic group. The temperature in the latter group had the tendency to drop much lower than in the former group. There did not seem to be any difference in the behaviour of temperature between experimental and control animals. However, one dibenzyline-haemorrhagic shock animal maintained its temperature to an average of 38° C throughout the experimental period. This same dog was a permanent survivor. On the whole, animals which survived either permanently or the longest, tended to stabilize their temperatures at an average of 34° C.

b) Blood Pressure--Ten to fifteen minutes after reinfusion, the mean blood pressure in both experimental and control animals went up to levels above 100 cm Hg. The mean values were however higher in dialysed dogs than in the controls. (Table IV) The dibenzyline control dogs were almost identical to the haemorrhagic shock and dialysis control group of animals. After the administration of .5 mg/kg dibenzyline, there was a gradual fall of blood pressure to levels as low as 50 mm Hg in thirty minutes. (Figs. 11 & 12) Seven out of ten dogs in this series showed this tendency. All the three permanent

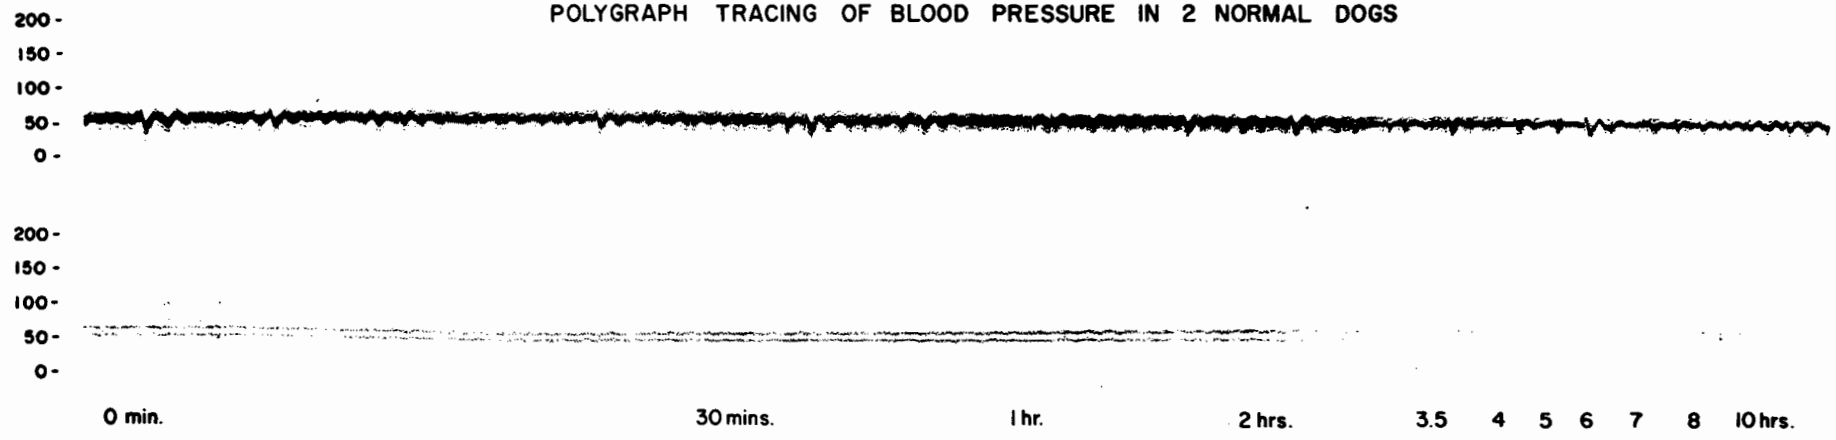

Fig. 11.--This is a normal polygraph tracing of two dogs which were not subjected to any form of experimental procedure. They were anesthetized with nembutal and their blood pressures were observed for over eight hours. Nembutal in pharmacological doses does not cause hypotension in a dog.

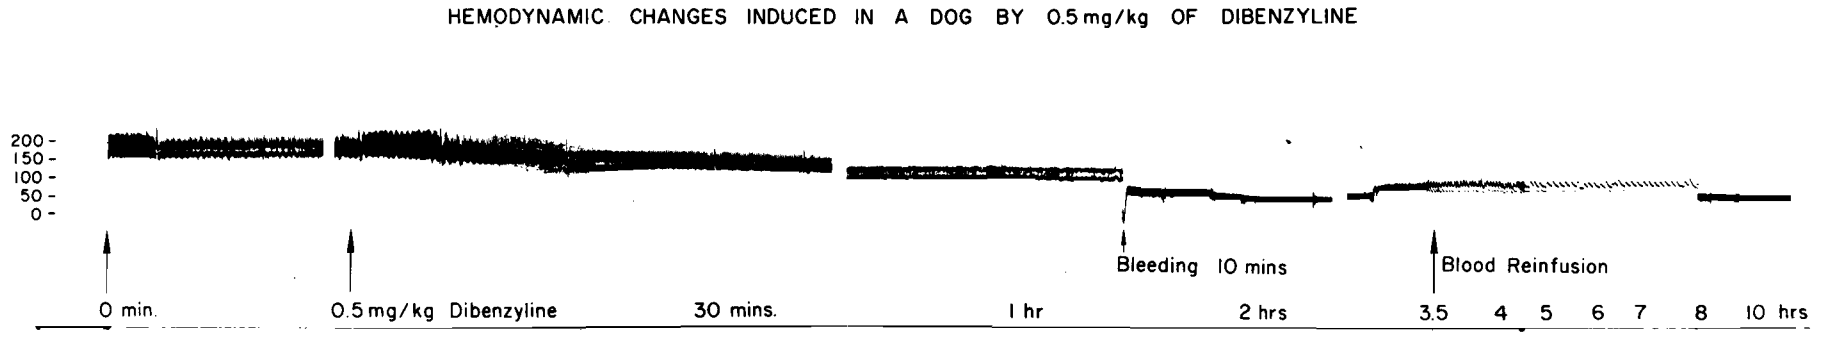

Fig. 12.--Administration of Dibenzyline (phenoxybenzamine) is accompanied by a gradual fall in blood pressure to levels as low as 50 mm Hg. In spite of this hypotension the other vital signs are not adversely affected.

survivors in this group had blood pressures below 100 mm Hg for the whole hour prior to the induction of the dogs into shock. They, however, showed elevation of their blood pressure above 100 mm Hg after reinfusion and maintained it to that level till the end of the experiment. One dibenzyline dog showed progressive fall of blood pressure after administration of the drug and died in three hours.

c) Heart Rate--There was a general tendency towards tachycardia as the animal went deeper into shock. This was seen in both control and experimental dogs. In fact the dialysed dogs' mean values were much higher than the control group. (Tables 14 and 16) The heart rate in this latter group went as high as 228 beats per minute. The dibenzyline dogs had mean heart rates lower than their control group. The seven dogs which died in less than five hours in this series showed a severe tachycardia, up to 300 beats per minute, fifteen to thirty minutes pre mortem. However, one dog, which survived permanently, also manifested a severe tachycardia, 300 beats per minute at the end of the experimental period.

d) Venous Pressure--There was an increasing depression of venous pressures from the normal average values of 6.5 cm water to levels as low as -2 cm water. Nine dogs in the haemorrhagic group showed venous pressures which were below zero degrees centigrade. One of these dogs was a permanent survivor. These subzero values usually appeared fifteen to twenty minutes after induction of shock. They remained at this level until reinfusion when the venous

pressure went up again to levels slightly below control values. Dialysed dogs manifested a tendency to increase venous pressures to normal values. As observed in the endotoxin dogs, there was always an elevation of venous pressures to averages of 16.5 cm water just before death.

e) Respiratory Rate--Some dogs were hyperpnoeic before the experiment was begun. Hyperventilation was a common feature of all dogs at the beginning of the bleeding period. One dialysed dog which died in 3½ hours had a respiratory rate of ninety per minute. There was a general tendency for the dogs to reach normal respiratory rates towards the end of the experimental period. All the nine permanent survivors in this group showed a tendency to adjust their respiratory rate to normal values. As a general rule, most dogs showed an increased respiratory rate in the middle of the experimental period. It is of interest to note that the dibenzyline dogs, except one, maintained a fairly normal respiratory rate (18-27) throughout the whole experimental period.

f) Blood Volume and Rate of Bleeding into the Reservoir--In all the control and experimental dogs, except the dibenzyline animals, the rate of blood flow into the reservoir had an average of 120-150 cc per minute, while the bleeding volumes averaged 40 cc/kg body weight. (Photograph VIII) At the end of induction of haemorrhagic shock, there was so much resistance in reinfusing the blood back into the dog that a 50 cc syringe had to be employed in order to reinfuse

the blood intraarterially. In the dibenzyline animals there was little resistance to reinfusion. It was also noted that most haemorrhagic shock dogs started autoreinfusion at the average time of seventy-nine minutes. In the dibenzyline group, six out of ten dogs did not reinfuse at all for 2½ hours. (Appendix XXII) (Table 20)

It is interesting to note that in all endotoxin and haemorrhagic shock dogs that were weighed, the average loss of weight during the experimental period was 1.5 kg.

4: EFFECTS OF TREATMENT ON SURVIVAL RATE (Tables 5, 6, 19, and Fig. 13)

a) Normal Dogs, Dialysis and Prophylactic Antibiotics--There were four out of ten (80%) permanent survivors in the dogs which received prophylactic fortimycin after haemodialysis. The average life span of the dogs which did not receive prophylactic antibiotics was 4.2 days. No dog in this group lived for more than five days.

b) Endotoxin Group--The total number of permanent survivors in the endotoxin group out of a total of seventy-three dogs (excluding six histamine dogs) was twenty-five. Of these dogs, six out of thirty-four controls were permanent survivors, while nineteen out of the thirty-nine experimental animals lived permanently.

In the endotoxin and early dialysis with new and old coils, there were eight permanent survivors out of twenty-eight paired dogs; one control and seven experimental. The mortality rate in the experimental group was fifty percent as compared to ninety-three percent in the control animals.

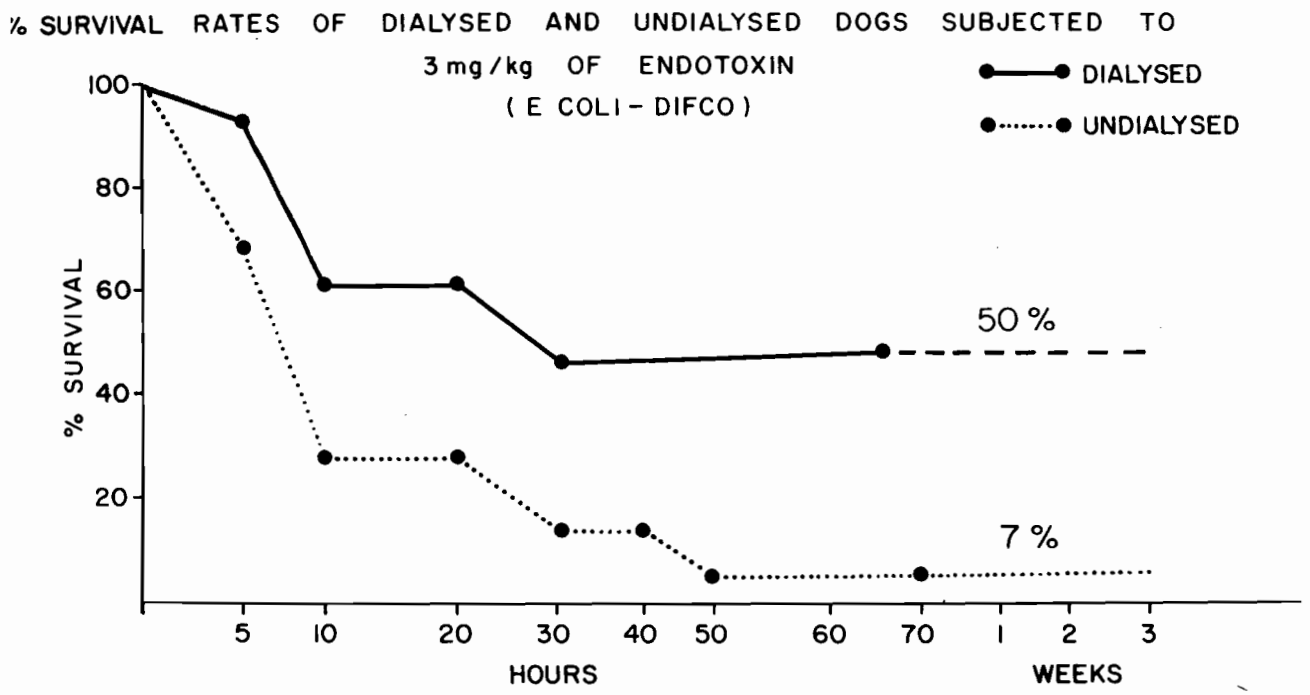

Fig. 13.--The highest mortality rate in both control and experimental dogs lies between one and ten hours. After this period, most dogs live permanently.

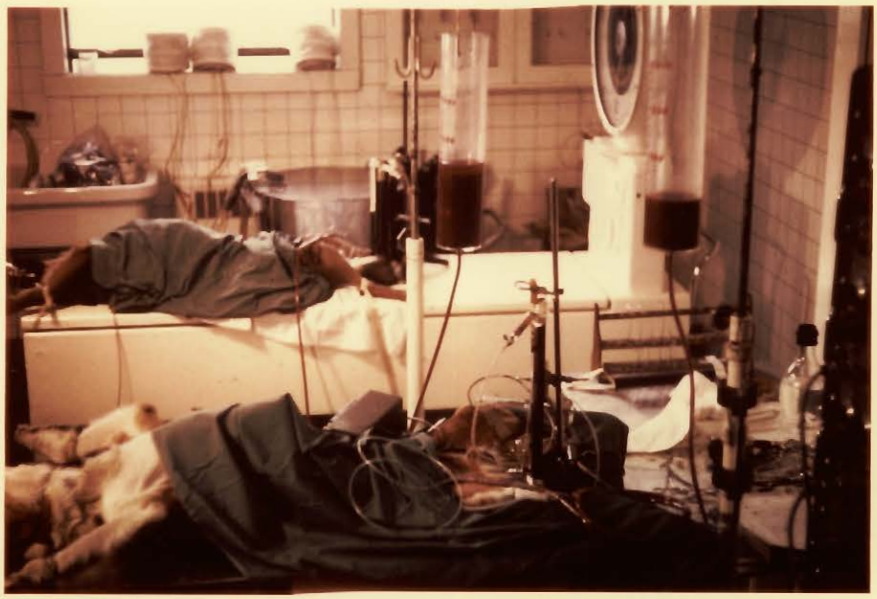
PHOTOGRAPH VIII



These two dogs have almost identical weights. Both dogs were subjected to Wiggers-Fine Technique of haemorrhagic shock. Both dogs have a blood pressure of 50 mm Hg. The dog on the Weight Scale Model 9281 (Toledo) has a bleeding volume of 1,100 cc of blood in the reservoir, while the dibenzyline dog in the foreground has a bleeding volume of 500 cc.

In the dogs that were dialysed early with new coils only, the survival rate was seventy percent out of a total of ten healthy mongrel dogs. Among the ten dogs out of fifteen that were dialysed $3\frac{1}{2}$-4 hours post endotoxin injection, five (50%) were permanent survivors while in the five control animals, there was only one (10%) permanent survivor. The survival rate of the mechanical-effects-of-dialysis dogs closely resemble that of all control dogs subjected to endotoxin. Out of ten dogs subjected to this procedure, only one lived up to twenty-eight hours. The mean survival time is almost identical with that in the control group of early dialysis; 10.1 hours and 10.4 hours respectively.

However, of the ten morphine dogs, four (40%) were permanent survivors. The experimental group had one (10%) permanent survivor out of five dogs, while the control dogs had three (60%) out of five permanent survivors.

c) Haemorrhagic Group--Out of a total of forty dogs employed in this experiment, nine (22.5%) were permanent survivors. In the ten animals subjected to haemorrhagic shock and hemodialysis, three (30%) were permanent survivors, while only two (20%) of the ten control dogs in this group survived permanently.

The control group of the dibenzyline dogs which resembled the control of the haemorrhagic shock and dialysis dogs, had one (10%) permanent survivor out of ten dogs. The other ten animals which received .5 mg/kg of dibenzyline had three (30%) permanent survivors.

PHOTOGRAPH IX

PHOTOGRAPH X

A piece of small intestine was taken from a dog which lived 8 hours after endotoxin injection. The mucosa looks oedematous and haemorrhagic. The same pathological findings were observed in non survivors subjected to haemorrhagic shock.

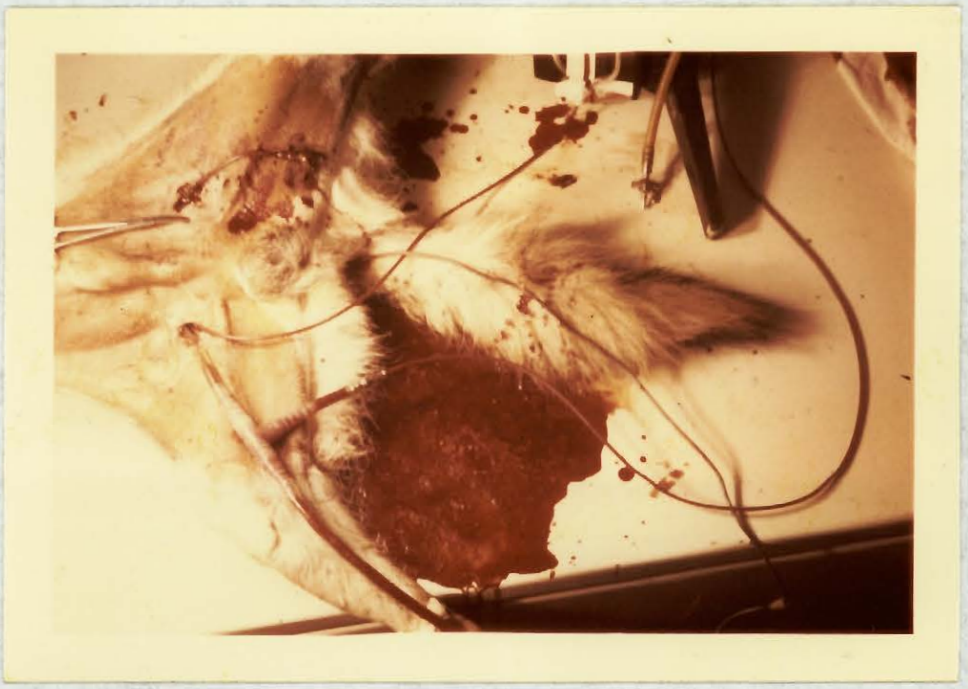
5: NECROPSY FINDINGS (Photographs IX and X)

All the ten normal dogs subjected to haemodialysis with or without antibiotics were autopsied. In those dogs which died and had not received antibiotics, the lungs were congested, haemorrhagic, soggy and covered with white-greyish mottled patches. The liver was also covered with these whitish lesions. These findings were highly suggestive of septicemia. Both large and small intestines were unremarkable. The permanent survivors who were donors, were also opened immediately after death, and no gross pathological lesions were noted in the viscera.

Ten of the endotoxin group that had died in shock were also autopsied. The significant findings were bluish purplish serosa of the small bowel from the upper jejunum to the ileum. On opening the small bowel, bloody yellowish fluid was found. The mucosa was oedematous, congested and haemorrhagic and some mucosal ulcerations were seen in some segments of the small bowel.

In the twenty haemorrhagic shock dogs, the same haemorrhagic phenomenon in the mucosa of the small intestine was noticed. In addition to these findings, the spleen was extremely contracted and rubbery in consistency. The five dibenzyline dogs that were autopsied did not show as much of a severe haemorrhagic necrosis of the bowel as the five control dogs. All the five permanent survivors that were sacrificed after thirty hours did not show these gross pathological

PHOTOGRAPH XI



BLOODY DIARRHOEA IN A HAEMORRHAGIC SHOCK DOG

This dog began having bloody diarrhoea after 2½ hours in haemorrhagic shock. The shed blood had already been reinfused into the dog.

PHOTOGRAPH XII

This is the appearance of a normal liver. Notice the beefy, reddish, healthy colouration of this organ.

PHOTOGRAPH XIII

After administration of 3 mg/kg of endotoxin to the same dog, the capsule becomes very tense. The liver becomes engorged with a tremendous amount of blood and it changes its normal colour to a blue-blackish appearance. These changes last for two hours or more.

changes.

Often some dogs would start having a bloody diarrhoea after $2\frac{1}{2}$-$3\frac{1}{2}$ hours in shock. (Photograph XI)

6: OTHER FINDINGS

Three histamine dogs, that were opened through a midline incision to visualize the liver, showed gross interesting changes in the liver as the dog went deeper into shock. The beefy-reddish appearance of the liver (Photograph XII) progressively became darker (Photograph XIII) to an almost black colour in one hour after the administration of endotoxin. The capsule became tense as the colour deepened. After two hours and a half of these observations, the liver did not seem to regain its normal colour.

7: EFFECTS OF ENDOTOXIN SHOCK AND DIALYSIS ON BLOOD CHEMISTRIES, ELECTROLYTES AND HEMATOCRIT IN DOGS

a) ELECTROLYTES (Tables 4 and 12) (Appendices IV, V, and VII)

In the endotoxin group, chemistries, electrolytes and hematocrits were determined in fourty-five dogs.

1. Chloride--The mean chlorides in both control and experimental dogs remained at practically the same level. There was a slight hyperchloremia at the end of $3\frac{1}{2}$ hours. Examining the individual values of the chloride anion, there is a general tendency of increasing plasma chloride as the dog goes deeper into shock. Nineteen dogs out of a total of forty-five endotoxin dogs showed this tendency of slight hyperchloremia with progressive shock.

2. Sodium--Plasma sodium shows the opposite tendency of the chloride anion in both dialysed and control dogs. Only six dogs in this series showed a slight increase in sodium cation as the dog sank deeper into shock. In fact, there was a progressive lowering of the mean sodium values in all the dogs.

3. Potassium--In dialysed dogs and in dogs subjected to endotoxin and mechanical effects of dialysis, there was a general fall of plasma potassium during the shock period. On the other hand, in the control group, there was a general increase in plasma potassium levels during the experimental period.

4. Hematocrit--Hematocrit levels increased with increasing shock except in dialysed dogs where the tendency at progressive falling or stabilization of hematocrits was observed. The mechanical-effects-of-dialysis dogs showed the same tendency.

b) CHEMISTRIES

1. pH --(Normal arterial blood chemistries are shown on Table 21.) The mean pH in all the endotoxin dogs which had been followed for three and a half hours was 7.33. However, in the endotoxin-mechanical-effects-of-dialysis dogs, that were followed for 270 minutes, the mean pH was 7.27. On the whole these dogs did not manifest an acidosis of significance.

DOG NUMBER	1	2	3	4	5
pH (Blood)	7.42	7.41	7.38	7.86	7.43
pH (Serum)	7.28	7.22	7.24	7.30	7.24
pCO_2 in mm Hg	32.3	27.8	32.0	37.2	28.0
Bicarbonate in meq/l	20.20	17.8	18.6	21.2	18.5
Lactic acid in meq/l	1.8	2.3	2.03	1.4	1.4

TABLE 21 (Continued)

ARTERIAL BLOOD CHEMISTRIES OF NORMAL UNANESTHETIZED DOGS
AFTER CORRECTION OF pCO_2 TO 40 MM, Hg

BB

DOG NUMBER	1	2	3	4	5
pH (Blood)	7.37	7.32	7.34	7.61	7.34
pH (Serum)	7.23	7.20	7.20	7.29	7.16
pCO_2 at 40 mm, Hg	40	40	40	40	40
Bicarbonate in meq/l	20.1	18.0	19.8	25.0	16.5
(Blood)	30	27.0	27.5	40.0	27.6
Lactic Acid in meq/l	1.8	2.3	2.0	1.4	1.4

However, in correcting the pCO_2 to 40 mm Hg, the pH becomes markedly lower from the average of 7.33 to 7.1, even as low as 7.0. The lowest mean pH was found in the haemorrhagic shock control dogs. (Table 18) On the whole, the dialysed dogs showed a higher pH than the controls. The controls on the other hand showed higher pH averages than the dogs subjected to endotoxin and the mechanical effects of dialysis.

2. pCO_2 -- The control dogs showed a reduction of pCO_2 from the control almost by half. This reduction was maintained throughout the experimental period. There is a similarity of mean pCO_2 in the endotoxin-mechanical-effects group and endotoxin control dogs. The mean pCO_2 in dialysed dogs was maintained at practically the same control value throughout the observation period.

3. Bicarbonate--There was a tendency in the control group to maintain its bicarbonate level at $9 \pm 1.f$ meq/l. Individual results showed that bicarbonate concentrations were markedly reduced during the first half hour of endotoxin shock. The endotoxin-mechanical-effects-of-dialysis dogs showed a marked depression of mean HCO_3^- during the experimental period. Dialysed dogs showed a fairly steady level of HCO_3^-. Even bicarbonate values of individual dogs showed this steady tendency. When the pCO_2 was corrected to 40 mm Hg, the bicarbonate values were much higher than the previous figures. (av. 6 meq/l)

4. Lactic Acid--There was a general tendency for gradual elevation of lactic acid from the control levels. Lactic acid in the endo-

toxin-mechanical-effect-of-dialysis dogs reflected the same tendency, as in the endotoxin control dogs. Dialysed dogs also showed a slight rise of lactic acid during the experimental period. The tendency towards elevation of lactic acid was noted in individual dogs as a whole.

In the endotoxin dogs, the chemistries were not markedly different from normal. However, when pCO_2 was corrected to 40 mm Hg, there was a drop in pH to very severe acidotic levels. On the whole, dialysed dogs seemed to retain higher pCO_2 values than the control dogs. Bicarbonate showed progressive depletion during shock. On correction of pCO_2 to 40 mm Hg, there was a tendency towards preservation of base bicarbonate to normal values. Lactic acidosis, although not very severe was observed in all dogs.

8: EFFECTS OF HAEMORRHAGIC SHOCK, DIBENZYLINE AND DIALYSIS ON BLOOD ELECTROLYTES, CHEMISTRIES AND HEMATOCRIT
(Appendices XIX, XXI, and XXIII)

a) ELECTROLYTES

1. Chloride--The two control groups in this series are almost identical. Mean chloride of the twenty dogs also manifested a tendency towards hyperchloremia at the end of 4½ hours. The mean values of chloride of this group markedly resembled the endotoxin control group. Dibenzyline dogs exhibit lower plasma chloride when compared with the controls. However, the dialysed haemorrhagic shock dogs did not have chloride mean values that were lower than the controls. In fact, the figures were very similar. On the whole, the dialysed endotoxin group showed lower mean plasma chloride than the dialysed haemorrhagic shock dogs.

2. Sodium--The mean plasma sodiumwas higher in the ten dogs which served as controls of the dialysed haemorrhagic shock dogs than in all the other thirty dogs in this group. There was little difference in plasma levels between the dibenzyline dogs and the dialysed haemorrhagic shock animals. Plasma values in this group generally resembled the endotoxin group.

3. Potassium--Potassium levels in control dogs showed a tendency to rise as the dog sunk deeper into shock, while dialysed haemorrhagic shock dogs manifested little changes from the control values. However, the dibenzyline dogs showed lower mean values by 2 meq/l of potassium throughout the experimental period. In all the endotoxin group, the potassium levels were much lower than in the haemorrhagic group.

4. Hematocrit--There was a general tendency in the elevation of hematocrit in the control dogs. While in the dibenzyline and the dialysed dogs, hematocrits seemed to remain fairly steady during shock. The hematocrit of the control in this group very much resembles the endotoxin and early dialysis control dogs. Both groups showed a general tendency towards hematocrit elevations as the dogs went into irreversible shock.

b) CHEMISTRIES

1. pH -- The pH in all the control dogs was extremely acidic for the first two hours. In one group of control dogs, the pH remained

at 7.1 plus a fraction until the end of the experiment. However, in the other ten control dogs, pH returned to preshock levels after reinfusion of the blood into the dog. While the ten dialysed haemorrhagic shock dogs also manifested a strong acidotic state for the first two hours, after reinfusion and dialysis, the pH went up markedly almost to control values after treatment. The dibenzyline group did not have a single mean pH which was below 7.2 throughout the whole experimental period. The pH remained at this high level during shock. It was also noted that in the endotoxin dogs, the pH reservoir blood was determined before reinfusion, the average was 7.34. Correcting the pCO_2 to 40 mm Hg, the control group showed a severe depression of pH to 7.0. However, in one control group of ten dogs, there was an elevation of pH to control levels at the end of the experiment. The control group that showed severe acidosis had two permanent survivors out of ten (20%) and mean survival hours of 12.2, while the other control group, which showed an elevation of pH to preshock levels at the end of 4½ hours, had one permanent survivor (10%) and an average survival time of 13 hours. The dibenzyline dogs, even after correction of pCO_2, did not show pH values below 7.1, while the dialysed haemorrhagic shock dogs still showed a slight elevation of pH during and after hemodialysis. The severity of the acidosis in corrected pH of the control in haemorrhagic dogs resembled the endotoxin-mechanical-effects-of-dialysis dogs.

2. pCO_2 -- In all the control dogs there was a tendency of marked reduction of pCO_2 from the control values. Sometimes these mean values were almost half the preshock values. It was noted that

pCO_2 was generally lowered by not less than 10 mm Hg during the period of shock. This same phenomenon was observed in dialysed haemorrhagic shock dogs. The dibenzyline dogs on the whole, while they reduced their pCO_2 by 5 mm Hg, were able to maintain it at the same level during the experiment. The pCO_2 values of dialysed endotoxin dogs very much resembled the dibenzyline haemorrhagic shock dogs. In the endotoxin animals, except for the dialysed group, the pCO_2 tended to be lower than in the haemorrhagic dogs. It was of interest to note that the blood reservoir pCO_2 did not fall below 33 mm Hg. (Table 18)

3. Bicarbonate--There was a progressive severe depression of bicarbonate in all dogs except the dibenzyline group, during the first 2½ hours of shock. There was a general tendency towards elevation of bicarbonate values after reinfusion and dialysis. Even the control dogs which were not dialysed showed this bicarbonate elevation towards the end of the experiment. One remarkable observation was that the dibenzyline group maintained their bicarbonate levels above 10 meq/l till the end. The reservoir pCO_2 stayed at the same control values.

Correcting pCO_2 to 40 mm Hg, the control haemorrhagic shock dogs show a severe depletion of base bicarbonate reserve to values as low as half the preshock levels. It was noted, even in the corrected bicarbonate concentration, that post reinfusion figures tended to be higher than the preceding shock values. Dibenzyline dogs preserved their base bicarbonate throughout the critical stages of shock. In this group there was no depletion of bicarbonate to levels as low as

those found in control dogs. Dogs subjected to dialysis showed an increase in base bicarbonate two times higher than the preceding values. Even in the endotoxin dogs, there was a general tendency of preservation of base bicarbonate throughout dialysis. It was also interesting to observe that in the endotoxin-mechanical-effects-of-dialysis dogs, which also received normal saline during the process, there was a progressive reduction of bicarbonate similar to the other control groups in endotoxin and haemorrhagic shock.

4. Lactic Acid--There was progressive elevation of lactic acid within half an hour to one hour of haemorrhagic shock. In the control dogs there was a reduction of lactic acid for the hour immediately following reinfusion of the reservoir blood into the dog. The dibenzyline dogs maintained a steady level of lactic acid. No value of lactic acid in this group exceeded 8.4 meq/l for 4½ hours. The experimental dogs showed a slight drop of lactic acid concentration following dialysis. Reservoir lactic acid was lower than the lactic acid in the dog. In contrast to the marked acidosis of the haemorrhagic dogs, the endotoxin animals manifested a low degree of lactic acidosis during shock; no values were higher than 6.0 meq/l in the endotoxin shock dogs.

CHAPTER V.

DISCUSSION.

An attempt has been made to demonstrate the efficacy of haemodialysis in the treatment of endotoxin and haemorrhagic hypotension. One hundred and thirty-four dogs were employed in this study. Seventy-nine were given 3 mg/kg body weight of endotoxin under various conditions of shock. Using a modified Wiggers-Fine technique, forty dogs were subjected to haemorrhagic shock, ten of which were dialysed.

The initial drop in blood pressure after initiation of dialysis is probably due to a decrease in venous return to the heart from the coil as a result of disparity in the volume of blood received by the dog and the volume of blood returning to the coil during the first few minutes of dialysis. It is possible that the femoral vein may be in spasm. This incipient drop in blood pressure after initiation of dialysis is seen in all dogs which undergo this form of treatment. When the animal has adjusted itself to this form of stress, the vital signs tend to level off to normal values. The period where all the parameters remained fairly constant is suggestive of a state of 'physiological equilibrium'. This is probably indicative of a period where perfusion of vital organs is satisfactory during dialysis.

It seems that regardless of what form of shock an animal is subjected to, there is a period where tachycardia is very much marked. This is usually seen after the animal has been in shock for two and one half hours. Tachycardia which was observed in many animals during shock was markedly less pronounced in dibenzyline dogs. Tachycardia is a compensatory circulatory mechanism. Since dibenzyline causes blood to be physiologically distributed in equal amounts to all parts of the body without preference to any particular organ, sufficient tissue perfusion and increased cardiac output may explain the relative absence of tachycardia in dibenzyline dogs subjected to haemorrhagic shock. As a whole, a tachycardia of over three hundred beats per minute indicates a poor prognosis. A progressively falling blood pressure is, in spite of transfusion, indicative of the irreversible stage. These two grave prognostic signs are also encountered in humans with bacteremic and haemorrhagic shock (Kinney et al, 1962), (Wilson, 1963). A dog whose systemic blood pressure stays above a hundred during dialysis and after reinfusion has a good chance of surviving longer or permanently. Probably the reason for this is that at this state the vital organs, notably the kidney, the intestines, the brain and the liver are well perfused and well oxygenated due to elimination of anoxia. The liver, by receiving sufficient nutrition, metabolises lactic acid efficiently and thus prevents occurrence of acidosis which enhances metabolic derangements that play an

important role in the irreversible phenomenon.

The initial dramatic period of hypotension which follows administration of endotoxin may be due to a sudden release of some vasoactive substance, possible histamine, but no significant amount of histamine in blood or plasma was extracted during this period. Perhaps a more sensitive technique is needed to exclude histamine as the cause of this dramatic post endotoxin injection hypotension. Schayer et al (1960 a, 1960 b) believe that histidine decarboxylase activity is markedly increased during the first two and one half hours of shock. Alican and Hardy (1961) found that this initial hypotension period of endotoxin shock was accompanied by elevation of portal vein pressure and an increase in thoracic duct lymph flow. The direct relationship between the hypotension itself and these physiological phenomena have not been established. Concomitant bradycardia is often noticed during this period. Heart rate may drop to levels as low as 80 beats/minute. It is possible that bradykinins and other allied kinins are released by endotoxin.

Administration of dibenzyline causes a dramatic fall of blood pressure not unlike that observed in endotoxin shock. The dibenzyline hypotension occurs ten to fifteen minutes after the administration of the drug. It is preceded by higher amplitudes on the polygraph tracing. This may be indicative of increased myocardial contractile strength which is partly responsible for

the increased cardiac output observed with this drug (Vassant et al, 1963), (Nicherson et al, 1959), (Vick et al, 1963).

Morphine as an 'anaesthetic agent' does not seem to cause as much hypotension as nembutal. This may explain why on the whole these dogs have higher blood pressure averages throughout shock than the nembutal dogs.

Hyperventilation is observed at the beginning of each haemorrhagic shock experiment and towards the end. This phenomenon is also observed with endotoxin administration. This initial hyperventilation is probably reflex in origin. The vasomotor respiratory centre attempts to adjust itself to the sudden onslaught by some noxious stimulus.

When the animal is already in shock or going into irreversible state another phase of compensatory hyperventilation is observed. The animal, in trying to compensate for the rising lactic acid, blows off CO_2. Thus the pCO_2 of haemorrhagic and endotoxin shock dogs is characterized by progressive fall as the dog sinks into irreversibility.

The dibenzyline dogs maintain a fairly constant temperature throughout the experimental period. The reason may be due to the less acidotic state of this group of dogs throughout the hypotensive period. In spite of the severe hypotension encountered in the dibenzyline dogs, there is less acidosis in this group than in the other groups of dogs subjected to the same pattern of hypotension.

Therefore the severity of hypotension in shock does not necessarily mean greater metabolic disturbances. There is no definite relationship between severe hypotension alone and the irreversible state. In spite of correction of hypotension by reinfusion of the shed blood and infusion of normal saline, 40% of the twenty haemorrhagic shock dogs went into irreversible state and died, while in endotoxin shock where thirty-four out of seventy-three dogs received no infusion at all, 66% survived permanently (Tables 6 and 19).

The venous pressures tend to rise at the beginning of each experiment from 10.7 to 14.1 cm of water (average 12.4) in normal dogs subjected to dialysis alone. In endotoxin shock dogs, the range of initial venous pressure is from 3.6 to 8.5 cm water (average 6.0) in both experimental and control dogs. In the haemorrhagic group of dogs, mean venous pressures ranged from 4.3 to 6.7 cm water (average 6.5). The depression of venous pressures in haemorrhagic shock sometimes to negative values may be a reflection of peripheral venomotor disturbances. Reinfusion of reservoir blood temporarily restored the venous pressure to normal levels, indicating that a temporary improvement in cardiac output and tissue perfusion follows restoration of blood volumes to normal.

The dogs, being lightly anaesthetized, were 'whining' at the beginning of the experiment. This grunting like respiration increased intraabdominal pressure (Val Salva Maneuver) and led to

rather elevated venous pressures. This also explains why the normal dogs subjected to haemodialysis alone showed the highest initial mean venous pressures. Terminal elevation of venous pressure is a reflection of decreasing venous return secondary to the failure of the 'pump' to function efficiently. It was also observed that some permanent survivors exhibited elevated venous pressures at the end of five hours. The reason for this was that the dogs were already recovering from shock and were ready to jump off the table. This behaviour was frequently observed in endotoxin-morphine permanent survivors.

The progressive fall of temperatures during haemorrhagic and endotoxin shock is summarized in the appendices. This progressive fall in temperature may be due to the dog's loss of heat to its ambient environment such as the scale and/or the room or it may be a reflection of decreased metabolic rate secondary to reduction of effective circulating blood volume to vital organs and thermoregulating centres of the brain. Temperatures of haemorrhagic shock dogs under the same experimental conditions showed a tendency to drop lower than the endotoxin dog's temperatures. This is suggestive of a metabolic rather than the environmental cause in the behaviour of temperature during shock (Vassant et al, 1963), (Longerbeam et al, 1963), since the both groups of dogs were exposed to the same environment during the experimental period.

That there is peripheral vascular resistance during haemorrhagic shock is shown by the great resistance to reinfusion of the reservoir blood into the dog after two and one half hours in shock. This is the reason why a 50 cc Luer Lock syringe had to be employed to reinfuse the dogs intraarterially. The resistance was hardly encountered in the dogs which were pretreated with dibenzyline. In fact, most of these dogs auto reinfused by mere elevation of the reservoir stand to a higher level.

This simple experimental observation stongly supports the arguments of those who advocate the use of ganglionic blockers during shock to overcome the vasospastic effects of endogenous catecholamines.

The average weight loss of a dog during five to six hours of haemorrhagic and endotoxin shock is 1.5 kg. This is probably due to evaporation and loss of water through the respiratory system. Out of ten dogs subjected to mechanical effects of dialysis, in spite of restoration of the weight lost during the experimental period, only 10% survived. This observation implies that replenishment of lost fluid alone does not alter the course of irreversibility.

The major blood changes in both haemorrhagic and endotoxin shock, particularly in the former, consists of decreases in arterial pH, pCO_2 and bicarbonate concentration with increases in the concentration of lactate. The pH of control arterial blood

varies between 7.28 and 7.44 (Dittmer, 1961) (Table 21) , averaging 7.33. During endotoxin shock, the pH of both experimental and control animals remained practically within normal limits ranging between 7.27 and 7.38 (average 7.34) while in haemorrhagic shock dogs, pH ranged between 7.12 and 7.38 (average 7.25). In the endotoxin group there was hardly any difference between the pH of dialysed dogs and that of the control dogs. The reason for this similarity may be that the dogs were not followed for a period of over five hours. Probably, if blood studies were made eight to ten hours after endotoxin administration, the pH might have shown significant acidotic levels. However Vassant, Weil et al (1963), working on patients with bacteremic hypotension, found no significant acidosis in these patients. Their blood pH value was also normal and the pCO_2 measurements showed no consistent values. Correcting the pCO_2 to 40 mm Hg the pH becomes highly acidic in both experimental and control dogs, ranging from 7.03 to 7.25 (average 7.14). The dialysed dogs do not show any significant correction of pH to normal values (Table 18).

After correction of pCO_2, haemorrhagic shock dogs show a very severe acidosis with the pH ranging from 7.0 to 7.37 (average 7.18). After initiation of dialysis there is a slight elevation of pH from 7.0 to 7.22. Dialysis does seem to counteract metabolic acidosis either by diluting the acids or by dialysing out lactic and phosphoric acids through osmolarity

gradient difference between the bath and the plasma.

Dibenzyline dogs show the least pH depression in haemorrhagic shock dogs. This attempt at maintaining a normal pH during haemorrhagic shock is perhaps indicative of the drug's ability to prevent aggregation of cells, improve tissue perfusion and counteract the formation and accumulation of metabolites. It seems that prevention of metabolic derangements and accumulation of tissue metabolites play one of the key roles in the irreversible phenomenon. Dibenzyline is antiadrenergic and therefore improves the tissue perfusion by relief of venous spasm, prevention of blood sequestration and collection of by-products of anaerobic metabolism.

It is also interesting to note that blood reservoir pH, pCO_2, bicarbonate and lactic acid were within normal limits (Table 18). This blood has not undergone the active anaerobic metabolism that goes on in a dog that is in shock.

Normal arterial pCO_2 in a dog ranges between 30.0 and 43.7 (average 36.4). There is general reduction of pCO_2 during haemorrhagic and endotoxin shock (Table 4). This is more marked in haemorrhagic shock dogs which did not receive any treatment. The general depression of pCO_2 was less marked in those dogs which were treated with dibenzyline. In both endotoxin and haemorrhagic shock dogs treated with dialysis there was less depression of

pCO_2 (Table 15). The increased pulmonary ventilation that occurs during shock is responsible for the general reduction of plasma pCO_2. The more severe the acidosis the more the animal hyperventilates in order to compensate. Reduction of pCO_2 leads to reduction in plasma bicarbonate concentration. The nature of the acid-base changes is shown by the graph on Figures 14 and 15 which show a positive relationship between bicarbonate concentration and lactic acid. This is indicative of the fact that the chief metabolite responsible for acidosis is lactic acid. As dibenzyline and dialysis correct acidosis to a degree, there is less reduction of pCO_2 in animals subjected to these two forms of treatment.

The same correlation between levels of lactic acid and pH were observed in both endotoxin and haemorrhagic shock dogs. The lower the pH the higher the lactic acid (Figs. 16 and 17). This finding confirms the previous observation that the chief cause of acidosis in these two forms of shock is lactic acid (Hardaway, 1962), (Cannon, 1918), although some other acid may help to aggravate the picture.

Bicarbonate of control arterial blood averaged 33.5 meq/l, ranging between 27.0 and 40 meq/l. During haemorrhagic and endotoxin shock, the values of bicarbonate show a general tendency towards reduction. However, in the dogs that were dialysed or pretreated with dibenzyline, there was a tendency

towards preservation of bicarbonate at higher levels. In the haemorrhagic shock dogs where bicarbonate is severly depressed at the end of two and one half hours, institution of dialysis raises the bicarbonate values to reasonably high values. This rise of bicarbonate following dialysis is significant when correlated with a concomitant rise in pH and depression in lactic acid. This finding is not so marked in control dogs. Dialysis does seem to correct metabolic acidosis during shock.

We can reasonably postulate that dialysis causes physiological preservation of base bicarbonate because the mechanical-effects-of-dialysis dogs, which also received saline, do not show this tendency of preservation of bicarbonate that is amply demonstrated in dialysed dogs (Tables 12, 15, 17, 18). This is more marked in endotoxin than haemorrhagic shock dogs. In the latter, dialysis does not seem to be capable of preserving bicarbonate. Dibenzyline, in this respect, is superior to dialysis.

Dibenzyline dogs show the slightest reduction of bicarbonate throughout the shock period. This was pointed out previously as due to better perfusion of all the organs of the body.

The lactic acid concentration of the blood of control animals varied from 1.4 to 2.3 meq/l. The increase in blood lactate that follows shock accounts for the acidosis that is encountered in this syndrome. This is more marked in haemorrhagic

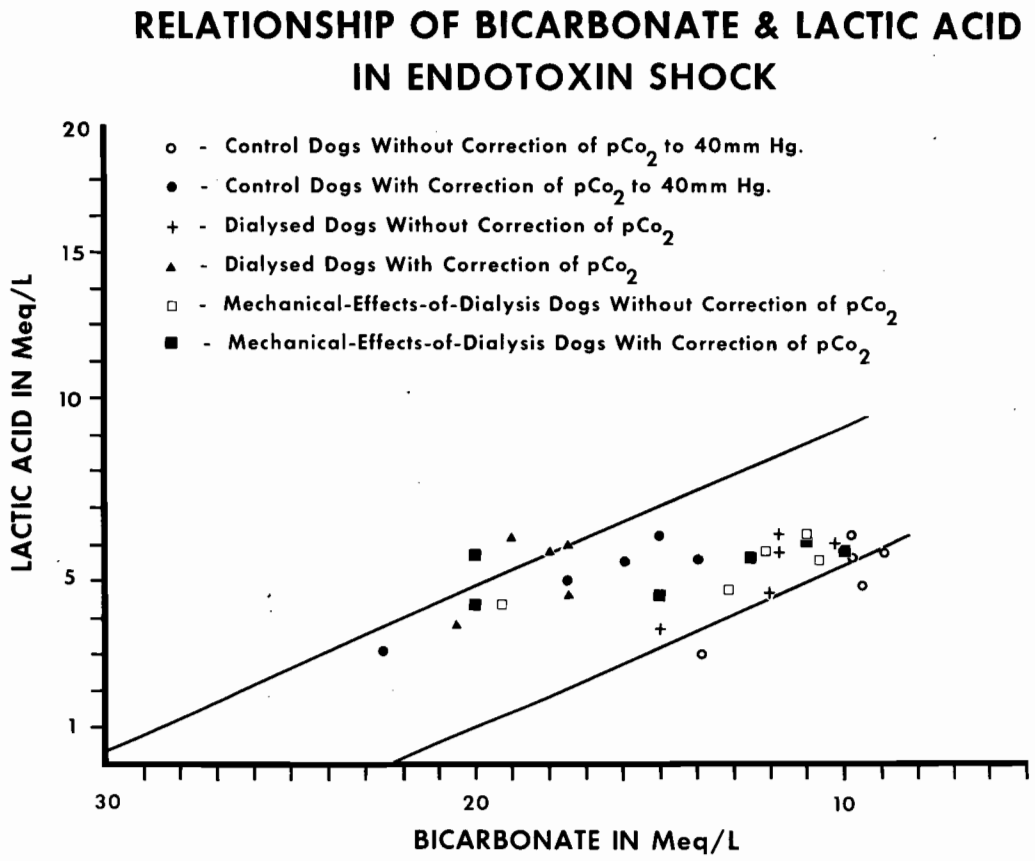

Fig. 14.-- This scattergram shows a positive relationship of bicarbonate to lactic acid in dogs subjected to endotoxin shock. Although pCO_2 is not corrected to 40 mm Hg that relationship is still well demonstrated - the lower the lactic acid the higher the bicarbonate.

than in endotoxin shock. This reflects the very severe lactic acidosis that is encountered in haemorrhagic shock. Prolongation of this state for over two and one half hours is fatal even though the acidosis and the hypovolemia are corrected. Endotoxin shock dogs show only a moderate increase in lactic acid during shock. This is probably due to the fact that the animals in this study were not in severe enough acidosis to reflect a marked change in lactic acid (Table 18). Following dialysis, there is a slight reduction of lactic acid in haemorrhagic shock dogs. Dilution effect of the saline may account for this fall since reservoir blood lactic acid was four times lower than the blood lactic acid. Since there is no marked lactic acidosis in endotoxin shock, dialysis does not produce any significant changes. Dibenzyline dogs were spared of severe lactic acidosis during the whole period of shock.

The progressive rise in hematocrit during shock is due to plasma loss (25% - MacLean and Weil, 1956), (7% - Grable et al, 1963). Whatever the amount of plasma lost, there is some progressive elevation of hematocrit during endotoxin shock. It is higher in haemorrhagic shock where some dogs show hematocrits as high as 63%. In dialysed haemorrhagic shock dogs, hematocrit tends to fall at the end of the experimental period while in endotoxin shock, hematocrit remains fairly constant. In both cases, this fall can be attributed to the infusion of 5% D/N.S.

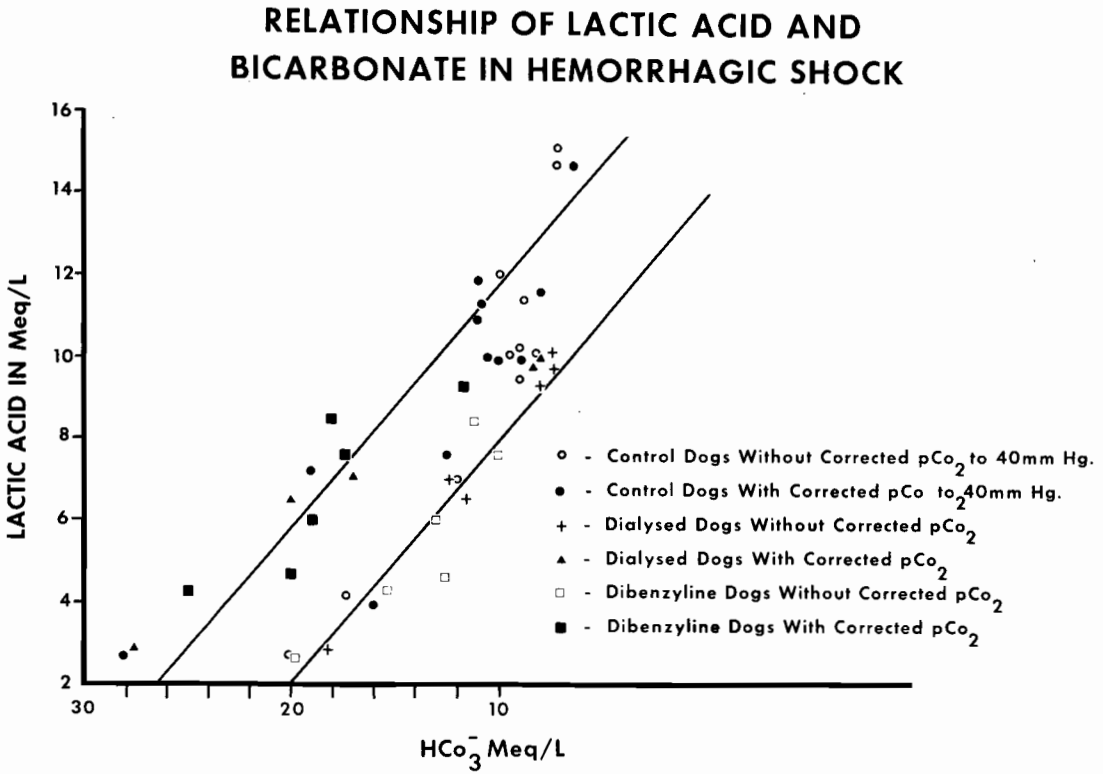

Fig. 15.--This graph is almost similar to Figure 14. It shows the same positive relationship between bicarbonate and lactic acid in haemorrhagic shock dogs. Lactic acidosis is very severe in this group of dogs and the depression of bicarbonate is quite marked even without correction of pCO_2 to 40 mm Hg. Elevation of bicarbonate is noted in dialysed and dibenzyline dogs.

during dialysis. Dibenzyline dogs show steady hematocrit values which are kept at levels close to normal throughout the experimental period. This observation supports the fact that dibenzyline prevents aggregation of cells and thus improves tissue perfusion.

The major changes in arterial blood electrolytes during shock are characterized by hyperkalemia and hyperchloremia in both control and experimental animals. This finding has been observed by other investigators in this field (Richards, 1943, 1944), (Wilson, 1963), (Wiggers, 1950), (Page, 1961). This is postulated to be due to emigration of the chloride and potassium ions from the cell to the extracellular space. There is general tendency towards hyponatremia as shock progresses. Dibenzyline and dialysis have a tendency to keep plasma sodium at normal constant values during shock.

The general fall in plasma potassium observed in dialysed and mechanical-effects-of-dialysis dogs is probably due to saline infusion while the hypokalemia may be the result of the dilution effect of 5% D/N.S. This reasoning is fortified by the fact that control groups which did not receive saline showed a general tendency towards hyperkalemia as pointed out before.

These changes in the blood constituents indicate the nature and the extent of some of the metabolic disturbances which occur when blood flow is slowed by decreasing the blood volume. Measurements of arterial pH, pCO_2 and lactate therefore

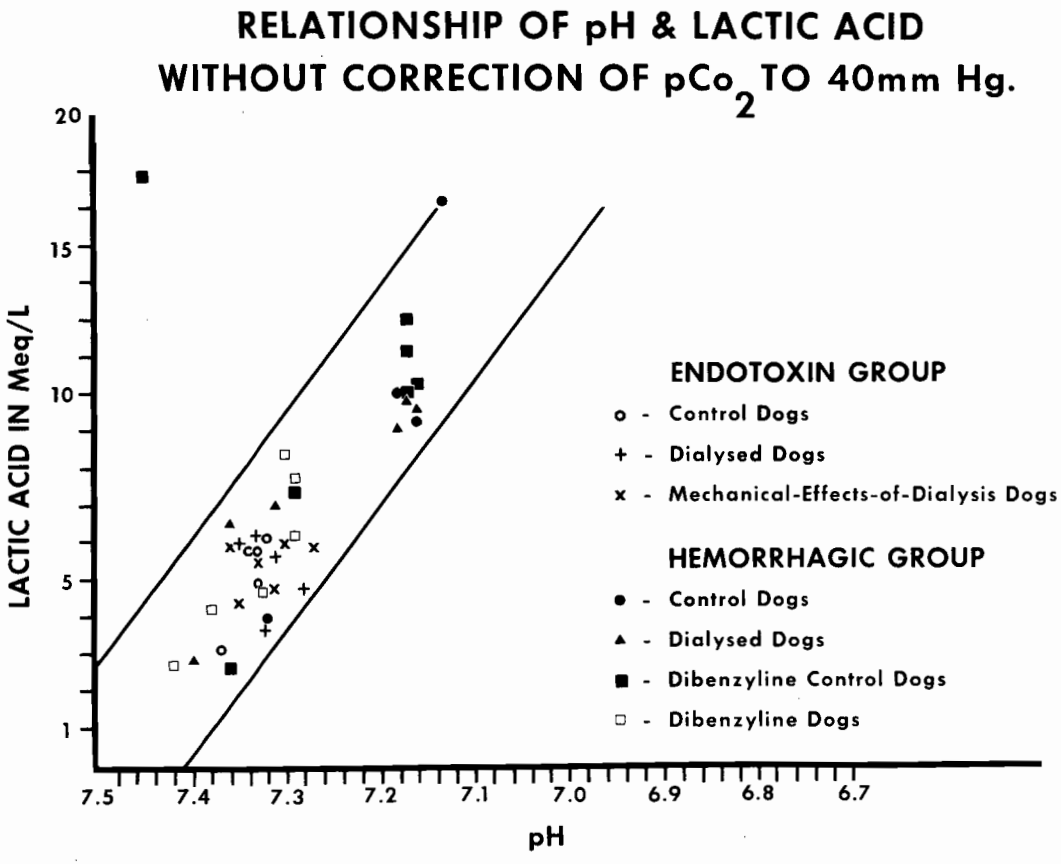

Fig. 16.--The rise in lactic acid is accompanied by pH depression and vice versa. Control dogs manifest a marked rise in lactic acid followed by depression of pH. Dialysed and dibenzyline dogs show comparatively low values of lactic acid.

provide further quantitative criteria not only for determining the depth or degree of shock, but also for testing at various stages the effectiveness of transfusion or any other therapeutic procedure.

One of the most interesting observations in these experiments is the correlation of survival time between the different groups of animals (Table 22). The survival time and percent survival rate in each experimental group of animals is summarized on Table 22. There is a definite correlation in survival time between the endotoxin control dogs and the endotoxin-mechanical-effects-of-dialysis animals. The former group had an average survival time of 10.4 hours while the latter averaged 10.1 hours. The two groups received 3 mg/kg endotoxin. Their main difference is that one group was subjected to the pumping effect of haemodialysis while the other group received no other form of trauma besides the endotoxin. Pumping the endotoxin shock dog without a kidney coil and bath or shocking the animal without any added insult have practically the same mortality rate. The survival rate of delayed dialysed dogs using old and new coils is 50% while that of early dialysed dogs with old and new coils is also 50%. This seems to point out that delayed dialysis does not seem to have a greater advantage over early dialysis in the treatment of endotoxin shock. The use of new sterile coils

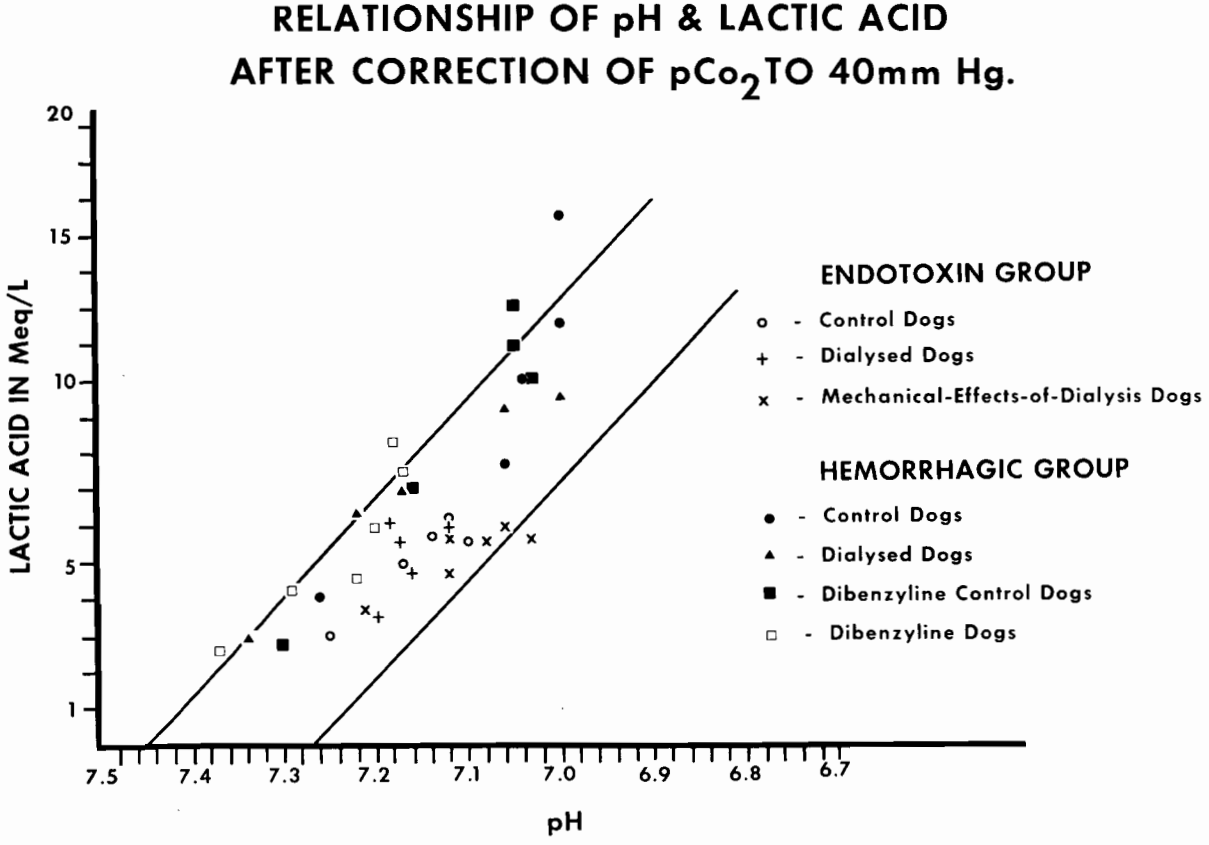

Fig. 17.--Even after correction of pCO_2 to 40 mm Hg, there is still a positive relationship between lactic acidosis and depression of pH. The control dogs in haemorrhagic shock show the highest concentrations of lactic acid. Dialysed and dibenzyline dogs show the least accumulation of lactic acid.

yielded 70% survival rate. The efficiency of the new kidney coil is reflected in the additional 20% survival rate. It is also noted that early dialysis or late dialysis have a mortality rate almost seven times as low as in the two control groups. These facts indicate that haemodialysis is of some value in bacteremic shock.

The fact that morphine-endotoxin-dialysed dogs had no permanent survivors while the controls had 60% survival rate is intriguing. It is very likely that morphine has a protective effect on a dog subjected to endotoxin. The dialysed dog was deprived of this protection as morphine was probably dialysed into the bath. Some pharmacological interaction between morphine and endotoxin, beneficial to the dog, may have been responsible for protecting the dogs from the lethal effects of endotoxin. A larger number of dogs is needed to interpret these findings statistically.

In the haemorrhagic shock dogs which were subjected to haemodialysis, only 30% survived while the controls in the same group had 20% survival rate. This is an interesting finding. It has been noted that haemorrhagic shock produces a marked state of lactic acidosis (Tables 15, 17 and 18) with marked depression of pH to levels as low as 7.0. We have also observed that in our experiments there is an apparent elevation of pH to 7.22 and base bicarbonate from 8.2 to 20 meq/l after dialysis

and a significant lowering of lactic acid from 9.7 to 6.5 meq/l coupled with an elevation of pCO_2 from 18 to 23 mm Hg. This is in contrast with the endotoxin group whose chemistries and electrolytes were practically within normal limits. In spite of hardly any acidosis during endotoxin shock, 50% of the early dialysed dogs died in irreversible shock, while the undialysed dogs in the same group had a mortality rate of 93%. In haemorrhagic shock, although correction of the pH is apparently accomplished by haemodialysis, yet the mortality rate is 70%.

Comparing the mortality rates of the endotoxin and haemorrhagic dialysed dogs and correlating them with the degree of chemical and electrolyte disturbances, it seems that while acidosis plays a role in the irreversible phenomenon of shock, it is not the chief actor on the stage since the drama can go on to the end with or without it. This conclusion is fortified by the observation of chemistries and electrolytes in dibenzyline treated dogs. Even though these dogs maintained their blood chemistries and electrolytes close to normal levels throughout shock, only 30% survived permanently.

The questions that come to our mind are: How do we account for better results of haemodialysis in the treatment of endotoxin shock? What are we dialysing in endotoxin shock which is not dialysable or absent in haemorrhagic shock? Could the substance or substances be catecholamines and/or histamine or could

this be some bacterial toxic product or is it the endotoxin itself that is dialysed out before it sauses irreversible damage to cells? It is possible that histamine and catecholamines are in greater concentration in endotoxin shock than in haemorrhagic shock. One important difference between these two groups is that dialysis, in spite of its correction of the acidotic state in haemorrhagic shock, does not seem to be of value in the treatment of this condition. One reason may be that when dialysis begins (two and one half hours after shock has begun), the animal is already in a state of irreversibility; thus at this stage this form of treatment appears to be an addition of another insult to injury.

CHAPTER VI.

SUMMARY AND COMMENTS.

1. One hundred and thirty-four dogs were employed in this series of experiments. One hundred and nineteen were subjected to experimental shock. Forty were subjected to haemorrhagic shock while seventy-nine dogs were given a lethal dose of E. Coli. Blood chemistries and electrolytes were determined in seventy dogs which were divided into: five normal, twenty-five endotoxin and forty haemorrhagic. Vital signs were recorded in all the dogs except five normal and six endotoxin dogs which did not require these parameters.

2. The review of literature on endotoxin and haemorrhagic shock was presented with special reference to the feasibility of employing haemodialysis in the treatment of these two forms of hypotension.

3. Dialysis is a relatively innocuous form of treatment which has been clinically employed for a wide variety of conditions which include: acute and chronic uremia, acute tubular necrosis, acute pancreatitis, acute glomerulo-nephritis, hemoglobinuric and myoglobinuric nephrosis, hepatorenal syndrome, acute renal failure supervening on existing renal disease, chemical nephrosis, salicylate and

barbiturate poisoning.

The artificial kidney can correct intractable oedema by ultrafiltration of 1,000-2,000 ml. in one hour (Kolff, 1954). Electrolyte derangements are encountered in many disease entities, many of which are associated with acute or chronic renal disease. Haemodialysis, if performed with enough caution, can restore electrolyte composition of blood plasma to normal more rapidly than can the natural kidney or any diuretic.

4. Haemodialysis was the principal form of treatment used in haemorrhagic and endotoxin shock. The results obtained with this form of treatment indicate that dialysis, if combined with antibiotics, cardiac glycosides and oxygen, has a place in the treatment of endotoxin shock.

It is also reasonable to conclude that if aseptic technique was used in conjunction with dialysis and antibiotics, more dogs could have survived the fatal effects of endotoxin.

5. Dibenzyline was used in a group of haemorrhagic shock dogs and its effect on blood chemistries and survival time has been discussed. Dibenzyline, while it produces hypotension by its sympatholytic action, also causes vasodilation of the vessels in those parts of the body where blood is most needed (heart, small intestine, liver and kidney). It appears that the greatest benefit rendered by dibenzyline in

haemorrhagic shock is in the opening up of the arteriolar portion of the circulation. This is so vital to tissue perfusion that even if shock is induced, anoxia does not take place so rapidly.

In spite of its apparent good effects on circulation, dibenzyline did not markedly improve the survival rate in animals subjected to haemorrhagic shock. It is possible that a larger dose than the one used in this series may give better results.

6. Morphine, for some obscure reason, seems to have some protective effect on dogs subjected to endotoxin shock. This observation needs more data to have some statistical value.

7. The major changes in blood chemistry and in acid-base balance which occur in haemorrhagic and endotoxin shock consist of progressive decreases in pH and arterial CO_2 content and progressive increases in the concentration of lactate and possibly phosphate. The metabolic acidosis, which is present during shock, is partly compensated for by a reduction in arterial CO_2.

There is no definite relationship between blood chemical derangements and survival in these series of experiments.

8. Dialysis has no place in the treatment of haemorrhagic shock. It could be useful if instituted before the onset of the irreversible stage.

CHAPTER VII.

CONCLUSION.

1. Dialysis of a normal dog without any secondary infection is compatible with life.

2. In endotoxin shock, haemodialysis, if instituted within five hours of infection, can prevent animals from going into irreversible shock. It is possible that some patients who are seen in the early phases of bacteremic shock may benefit from this type of treatment since the mortality in this form of hypotension is still high.

3. Endotoxin must release some toxic by-product, which contributes towards irreversibility and this substance or substances must be dialysable.

4. Combination of haemodialysis with antibiotics in treating endotoxin shock must yield better results than haemodialysis or antibiotics alone.

5. Haemodialysis is not an effective treatment of haemorrhagic shock. It may however be useful if used before irreversible changes have taken place.

6. Haemorrhagic shock produces a very severe acidosis, correction of which does not seem to alter the fatal trend in the majority of animals. Less metabolic derangements are encountered in endotoxin shock.

7. The major changes in the arterial blood chemistries and electrolytes after haemorrhage and endotoxin administration consist of decreases in the pH, pCO_2 and sodium and increases in lactate and potassium.

8. While metabolic acidosis is postulated to play an important role in the irreversible phenomenon, it does not seem to play a vital role, since its correction or absence does not necessarily reverse the fatal trend of shock.

9. Dibenzyline, while maintaining chemistries and electrolytes at near normal levels during haemorrhagic shock, does not increase the number of survivors.

10. Progressive fall in blood pressure in spite of dialysis or any form of treatment is indicative of a poor prognosis in any form of hypotension.

11. Replacement of fluid lost by the dog does not necessarily avert the irreversible trend.

12. Hypotension or olegemia alone cannot be responsible for the metabolic and electrolyte derangements in shock because dibenzyline dogs, in spite of their prolonged and severe hypotension, exhibit less metabolic derangements than the other group of dogs with higher blood pressures.
