Abstract

The reaction of (η -Arene)Cr(CO)₂(CX) (X = S, Se) complexes with excess (RO)₃P (R = Me, Et, n-Bu, Ph) yields Cr(CO)₂(CX)[(RO)₃P]₃, predominantly as the mer I isomer, in which a phosphite ligand is trans to CX. Arene displacement from (η -C₆H₆)Cr(CO)₂(CX) by tridentate phosphine ligands L-L-L [L-L-L = (Me)C(CH₂P(Ph)₂)₃, (Ph₂PCH₂CH₂)₂PhP] gives fac-(L-L-L)Cr(CO)₂(CX) products. The molecular structures of Cr(CO)₂(CX)[(MeO)₃P]₃ have been determined by single crystal X-ray diffraction. Intramolecular isomerization of these complexes as well as their tricarbonyl analogue has been demonstrated and activation parameters have been calculated for the rearrangement processes. Two-dimensional ³¹P NMR spectroscopy has provided evidence that isomerization occurs via trigonal prismatic intermediates. Kinetic investigations of the reaction of (η -C₆H₆)Cr(CO)₂(CX) with (MeO)₃P have established a first-order rate dependence on both the complex and the entering ligand. The faster reaction rate of the selenocarbonyl derivative relative to its thiocarbonyl analogue originates in a lower entropy of activation in the former case. The effect on the reaction rate of variation in the nature of the arene and of the entering ligand has been investigated.

An approach to hormonal receptor assay involving the detection by FT-IR spectroscopy of Cr(CO)₃-labelled modified estradiol bound to estrogen receptors in target tissue is reported.

The FT-IR spectra of FeTPP(CX) [FeTPP = (5,10,15,20-tetraphenylporphinato)Fe(II); X = S, Se] and FeTPP(CX)L (X = S, Se; L = pyridine, ethanol) have been obtained. Some changes in the porphyrin spectrum were observed with variation or removal of L, but not with variation of X.

CHALCOCARBONYL CHEMISTRY: APPLICATION IN
HORMONAL RECEPTOR DETERMINATION, METALLOPORPHYRINS
AND METAL-ARENE BOND ACTIVATION

Résumé

La réaction des complexes (*n*-arène)Cr(CO)₂(CX) (X = S, Se) en présence d'excès de (RO)₃P (R = Me, Et, *n*-Bu, Ph) produit Cr(CO)₂(CX)[(RO)₃P]₃, avec la prédominance de l'isomère mer I, chez lequel le ligand phosphite est en position trans du groupe CX. Le remplacement du groupe arène des complexes (*n*-C₆H₆)Cr(CO)₂(CX) par les ligands phosphines trientates L-L-L [L-L-L = (Me)C(CH₂P(Ph)₂)₃, (Ph₂PCH₂CH₂)₂PhP] conduit aux dérivés fac-(L-L-L)-Cr(CO)₂(CX). Les structures moléculaires des complexes Cr(CO)₂(CX)[(MeO)₃P]₃ ont été déterminées par diffraction des rayons-X des cristaux uniques. L'isomérisation intramoléculaire de ces complexes et de leurs analogues tricarbonylés a été démontrée, et les paramètres d'activation ont été calculés pour les processus de réarrangement. La spectroscopie RMN ³¹P bidimensionnelle a procuré des évidences montrant que l'isomérisation survient via des intermédiaires "prismatiques trigonales". Les études cinétiques de la réaction des complexes (*n*-C₆H₆)Cr(CO)₂(CX) avec (MeO)₃P ont établi la dépendance de la vitesse de premier-order pour chacun, le complexe et le ligand. Le dérivé sélénocarbonylé possède une vitesse de réaction la plus rapide relativement au dérivé thiocabonylé, laquelle provient d'une entropie d'activation plus faible. L'effet sur la vitesse de la réaction de la variation de la nature du groupe arène et du ligand substituant a été étudié. Une approche sur l'analyse des récepteurs hormonaux par détection des récepteurs estrogènes liés à des estradiols marqués de Cr(CO)₃ par spectroscopie IR-TF dans des tissus cibles est rapportée.

Les spectres IR-TF des complexes FeTPP(CX) [FeTPP = (5,10,15,20-tetraphenylporphinato)Fe(II); X = S, Se] et FeTPP(CX)L (X = S, Se; L = pyridine, éthanol) ont été obtenus. Quelques changements dans le spectre du groupe porphyrinique ont été observés avec la variation ou l'absence du ligand, et non pas avec la variation du groupe X.

Acknowledgements

I would like to thank Dr. Ian S. Butler for his guidance, support and encouragement. I would also like to express my deepest appreciation to Jacqueline Sedman for the many helpful discussions during the course of this work and for her valuable comments and suggestions in reading this thesis.

I also wish to express my gratitude to:

- Dr. Gérard Jaouen and Dr. Anne Vessières of l'Ecole Nationale Supérieure de Chimie de Paris for providing all the samples for the investigations reported in Chapter 6 of this thesis, and for their hospitality during my visit to Paris;

- Dr. Françoise Sauriol for obtaining the 2-D NMR spectra, for introducing me to 2-D NMR techniques and for her contributions to the elucidation of the mechanism of stereochemical nonrigidity;

- Paul Fitzpatrick for providing some samples of (η -Arene)Cr(CO)₂(CS) complexes;

- Drs. D. Mansuy and J.P. Battioni of Laboratoire de Chimie de l'Ecole Normale Supérieure, Paris, for providing iron tetraphenylporphyrin complexes;

- Dr. Peter Bird of Concordia University for introducing me to crystallographic techniques and for the determination of the crystal structure of Cr(CO)₂(CS)[(MeO)₃P]₃;

- Drs. Jean-Jacques Bonnet and Salomon Askenazy of the CNRS Laboratoire de Chimie de Coordination, Toulouse, France, and Dr. Ian Butler for the crystal structure of $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$;

- Dr. Barbara Gour for her advice on kinetic measurements;

- Dr. Bernard Belleau for permission to use the Cary 210 UV-vis spectrometer;

- Mr. Fred Kluck for his contribution to the design of specialized apparatus required during the course of this work;

- Ms. Carla Durston for her care in the final correction of the thesis;

- Pierre Harvey for his skillful drawing of figures;

- Dr. Rita Werbowyj for proofreading the final draft of the thesis.

The financial support of McGill University, in the form of the Coll McFee Memorial Scholarship and the McConnell Memorial Fellowship, of NSERC and of le Gouvernement du Québec is gratefully acknowledged.

Introduction

Since the first synthesis of an $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ complex in 1957 [1], the chemical reactivities of this class of complexes have been extensively investigated. Among the major and, from a practical point of view, most important findings of such studies is the utility of $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ complexes as catalysts in a variety of systems, particularly in the hydrogenation of dienes. The catalytically active species in the latter case has been established to involve partial or total loss of the arene [2,3].

The first syntheses of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CS})$ and $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CSe})$ complexes were reported in 1974 [4] and 1975 [5], respectively. Although the physical properties of these thio- and selenocarbonyl derivatives have been examined extensively, studies of their chemical behaviour have been limited. A striking aspect of their reactivity is a markedly enhanced arene lability relative to their tricarbonyl analogues, as evidenced by their reaction with CO under mild conditions to yield the corresponding penta-carbonyl complexes, $\text{Cr}(\text{CO})_5(\text{CS})$ and $\text{Cr}(\text{CO})_5(\text{CSe})$ [6]. In view of the nature of the catalytically active species formed from $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ in the hydrogenation of dienes it could reasonably be anticipated that $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S, Se}$) complexes would be excellent catalysts for such processes. However, investigation of such complexes as

catalysts has revealed that they completely lack activity [7].

Part I of this thesis concerns the study of arene lability in arene chromium chalcocarbonyl complexes. This research was undertaken to extend the known chemistry of thiocarbonyl and selenocarbonyl complexes, to obtain quantitative measurements of arene labilization in (η -Arene)-Cr(CO)₂(CX) (X = S, Se) and to probe the reasons for their reported inactivity as catalysts. Chapter 1 presents a brief review of mechanistic studies of (η -Arene)Cr(CO)₃-catalyzed hydrogenation of dienes to monoolefins. In Chapter 2, the reactions of (η -Arene)Cr(CO)₂(CX) (X = S, Se) with tertiary phosphite and tridentate phosphine ligands will be described. The spectroscopic properties of new thio- and selenocarbonyl complexes obtained, as well as the crystal structures of two typical products, will be presented, followed, in Chapter 3, by an investigation of stereochemical nonrigidity in these systems. The kinetics and mechanism of arene displacement from (η -Arene)Cr(CO)₂(CX) (X = S, Se) by tertiary phosphites will be the subject of Chapter 4, which concludes Part I.

In Part II, the combined use of FT-IR spectroscopy and metal chalcocarbonyl chemistry in two different types of biological applications will be demonstrated. While infrared spectroscopy has been among the major techniques

employed in the study of organometallic complexes throughout the history of organometallic chemistry, its application in the study of biological systems has been fairly limited in the past. This situation has largely been due to the complexity of such systems and the presence of biomolecules of interest in low concentration, as well as the unsuitability of water as an IR solvent. The recent development of FT-IR spectroscopy has led to the alleviation of these problems, as described in Chapter 5. Chapter 6 concerns a novel application of FT-IR spectroscopy and arene chromium chalcocarbonyl chemistry in a biological system: the incorporation of a $\text{Cr}(\text{CO})_3$ moiety in a biological molecule as a label for detection by FT-IR spectroscopy. In a collaborative project with Drs. G. Jaouen and A. Vessières of l'Ecole Nationale Supérieure de Chimie de Paris, $\text{Cr}(\text{CO})_3$ -labelled hormonal steroids have been bound to receptors in their target tissue. The subsequent detection of the carbonyl label by FT-IR spectroscopy and the potential utility of this procedure as an alternative to radioisotopic methods in receptor assay will be described in Chapter 6. An FT-IR study of chalcocarbonyl ligands coordinated to metalloporphyrins will be presented in Chapter 7. This represents an example of the use of FT-IR spectroscopy in the study of biological model compounds.

Finally, a summary of the contributions to knowledge,

suggestions for future work, and a list of publications and papers presented at scientific conferences which pertain to this work are given.

PART I

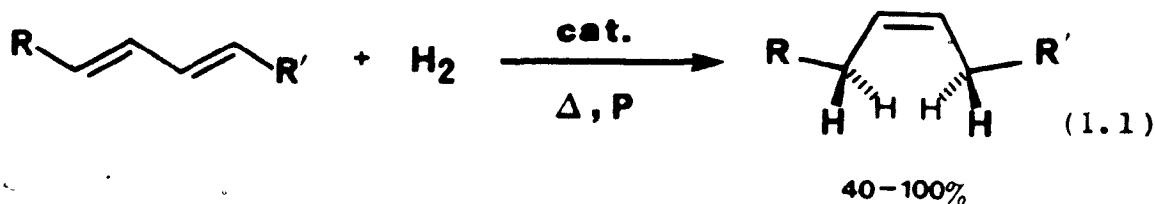

**Metal-Arene Bond Activation in
Arene Chromium Chalcocarbonyl Complexes**

Chapter 1

Catalytic Activity of Arene Chromium Chalcocarbonyl

Complexes

(η -Arene)Cr(CO)₃ complexes have found extensive use as catalysts in a variety of systems [1,2]. Among the most important catalytic applications of this class of compound is the hydrogenation of dienes to monoolefins [2-6]. As homogeneous catalysts (η -Arene)Cr(CO)₃ complexes effect stereospecific cis-addition of H₂ to one double bond of the diene with some regioselectivity [Eq. 1.1].

The conditions required for efficient catalysis depend critically on the nature of the arene. For monosubstituted arenes, high hydrogen pressure (30-50 atm) and high temperature (150-200°C) are needed (Table 1.1). The presence of electron-withdrawing substituents on the arene, which weaken the metal-arene bond, accelerates the rate of hydrogenation and shortens the induction period. However, polycyclic derivatives are even more favourable; for instance, with (η -anthracene)Cr(CO)₃ and (η -naphthalene)Cr(CO)₃ efficient

hydrogenation is achieved under mild conditions (80°C , 1 atm H_2) [4]. This is particularly advantageous and leads to a much cleaner reaction since decomposition of the catalyst, which occurs at higher temperature, is eliminated and unwanted side reactions are minimized. Also, less H_2 pressure is needed, thereby reducing cost.

From the observations concerning the variation of catalytic behaviour with change in arene-metal bond strength, the catalytically active species has been postulated to result from partial or total arene loss [1,3,5]. Two mechanisms have been proposed: Frankel *et al.* [2] postulated a dissociative mechanism in which the (η -Arene) $\text{Cr}(\text{CO})_3$ complex totally dissociates into arene + $\text{Cr}(\text{CO})_3$. The catalytically active species is subsequently produced by reaction of the $\text{Cr}(\text{CO})_3$ moiety with H_2 to give a dihydride which then reacts with a diene to afford 1,4-cis-addition of hydrogen, forming the monoene (Figure 1.1). Cais and Rejoan [3,5] later proposed an associative mechanism (Figure 1.2), involving a stepwise displacement of the arene, resulting in slippage of the arene to occupy ultimately a single coordination site of the metal (path a) or eventual total loss of arene (path b). The initial step involves the reversible dissociation of one double bond of the arene, followed by attack of the diene substrate. This is supported by the experimental observation that heating the substrate in the absence of H_2 ,

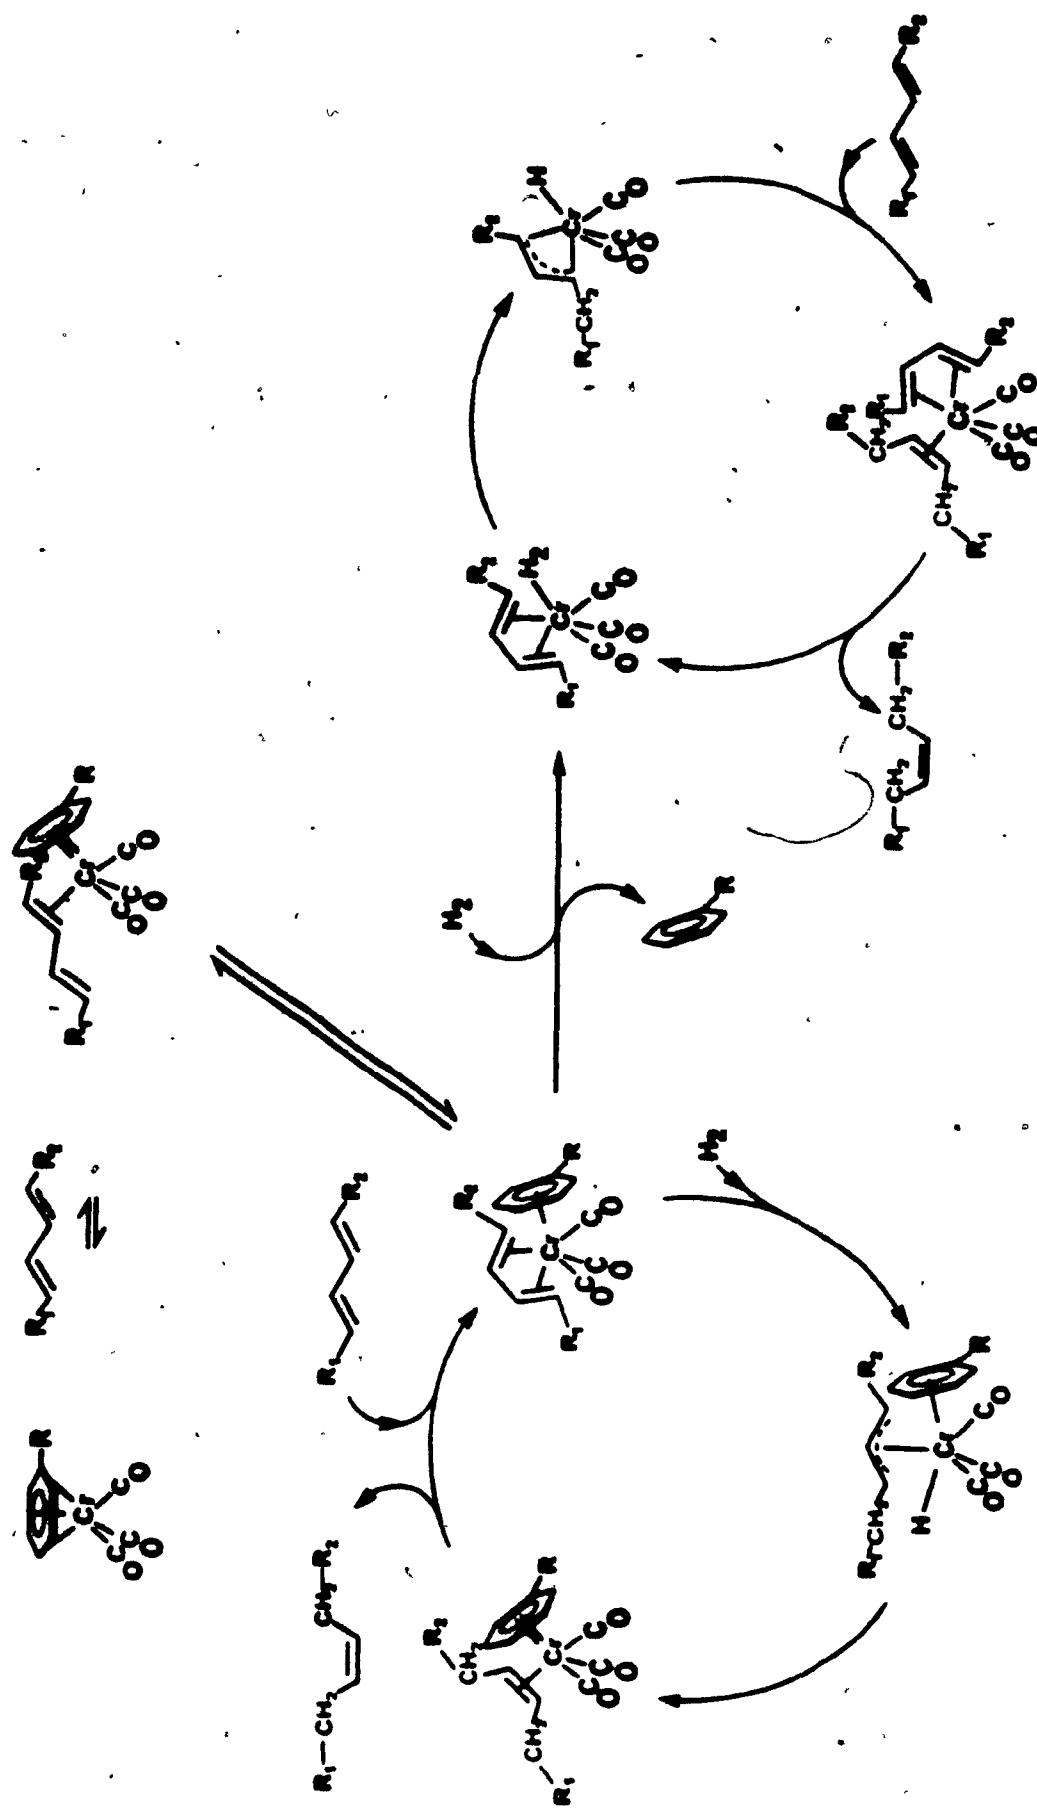

Figure 1.2. Mechanism proposed by Cai and Reijoen for the (η -Arene) $\text{Cr}(\text{CO})_3$ -catalyzed hydrogenation of dienes to monoenes. Adapted from Reference 5.

followed by the introduction of H_2 , eliminated the induction period for the onset of hydrogenation. Conversely, heating the catalyst in the presence of H_2 did not alter the induction period significantly [3].

In order to investigate the true nature of the catalytic species, the $Cr(CO)_3(THF)_3$ species has been formed in situ by reaction of $(\eta\text{-Arene})Cr(CO)_3$ with THF as solvent [7]. It was found that addition of substrate to a solution containing this species effects catalysis at maximum rate with the elimination of the induction period normally seen with $(\eta\text{-Arene})Cr(CO)_3$. Also, addition of arene inhibited the reaction. Therefore, the catalytically active species in the hydrogenation of dienes appears to be formed by the total loss of arene in the presence of a coordinating solvent. In a separate kinetic investigation arene displacement has been found to occur via a stepwise displacement of the ring by the entering ligand [4], thus supporting path b of Cais and Rejoan's mechanism.

As indicated in Table 1.1, various attempts have been made to improve catalytic performance by experimenting with a variety of arenes [3-5,7]. However, the metal-arene bond strength in complexes of this type and consequently the ease of labilization of the arene which has proven necessary for effective catalysis is also a function of the electronic properties of the other ligands bonded to the metal. There-

fore, substituting a carbonyl group by another ligand will also modify the catalytic behaviour of the complex. This is of particular interest in the expectation that the use of a catalyst of the type (η -Arene)Cr(CO)(L)(L") would enhance the regioselectivity of the catalytic process [8-10].

The catalytic behaviour of complexes in which one of the carbonyl ligands has been replaced by a tertiary phosphine has been investigated [11,12]. The results for the hydrogenation of norbornadiene at 170°C under H₂ (48 atm) with these complexes are given in Table 1.2. It is apparent from these results that incorporation of a phosphine ligand into the catalyst brings about serious deterioration or total loss of catalytic activity. This has been attributed to two possible effects. First, the steric effect caused by the substituents on the phosphine may hinder the binding of the substrate. Secondly, the stronger σ -donor and weaker π -acceptor properties of the phosphine relative to CO lead to an increased electron density at the metal, resulting in strengthening of the metal-arene bond due to increased metal \rightarrow arene π -back-donation [11,12]. One then concludes that ligands chosen to replace CO should be similar to CO in their electronic properties.

Another ligand type with analogous binding properties to those of CO is the isocyanide CNR (R = alkyl or aryl). Initial testing of these complexes for catalytic activity

proved disappointing (Table 1.2) [11], indicating that the isocyanide ligands used were similar in bonding properties to tertiary phosphines. Dabard *et al.* [11] postulated that with the proper modification of the R group through the introduction of an N-acyl moiety [CNC(O)R] the π -acceptor properties of the isocyanide could be enhanced sufficiently to effect ring lability under catalytic conditions. Preliminary testing of these complexes proved that they indeed possessed catalytic activity superior to that of (η -Arene)-(CO)₂(CNR) [11]. Hence an increase in the π -acceptor properties of the isocyanide ligand was found to enhance catalytic activity.

Among the coordinating ligands that exhibit similar binding properties to those of CO and are known to be stronger π -acceptors than CO are the thiocarbonyl and selenocarbonyl ligands [13]. They thus appear to be very suitable candidates for enhancing the accessibility of the catalytic species. However, an investigation of the catalytic activity of (mbz)Cr(CO)₂(CS) (Table 1.2) has shown the thiocarbonyl complex to be one of the worst catalysts for the hydrogenation of dienes tested [11]: Under mild conditions no reaction took place, while at higher temperatures total decomposition of the complex was observed [11].

In the next chapter, the reactivities of Group VIB metal thiocarbonyl and selenocarbonyl complexes will be

reviewed. Investigations of arene displacement reactions of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S}, \text{Se}$) complexes will then be presented. Subsequently, the kinetic studies of such reactions will be described, and the results compared to those for analogous carbonyl complexes. This should provide some reasons for the lack of catalytic activity of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CS})$ complexes and give some indication as to the catalytic potential of the corresponding selenocarbonyl complexes in the hydrogenation of dienes to monoolefins.

Chapter 2

Reactions of (η -Arene)Cr(CO)₂(CX) (X = S, Se) Complexes with Tertiary Phosphites and Tridentate Phosphine Ligands

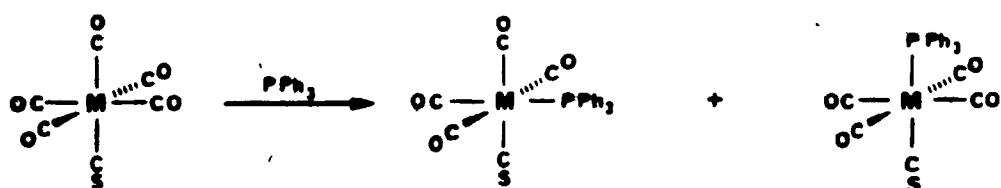

2.1 Thermal Reactivity of Group VIB Metal(0) Thiocarbonyl and Selenocarbonyl Complexes

The bonding properties of the thiocarbonyl and selenocarbonyl ligands in Group VIB metal complexes have been investigated extensively by a variety of spectroscopic and other techniques [1,2]. The two spectroscopic methods which have been most widely used are vibrational [2-7] and ¹³C NMR spectroscopy [5,8-10]. Other investigations have employed ¹⁷O NMR [11], photoelectron [12,13], electronic [5,14], and mass spectroscopy [15], and ESCA [16]. The body of evidence thus obtained has revealed that both the thiocarbonyl and selenocarbonyl ligands are stronger σ -donors and π -acceptors than CO in complexes with low oxidation state metals. For instance, in the case of IR studies, comparison between the carbonyl stretching force constants of π -bonded arene metal tricarbonyl complexes and those of their corresponding thio- or selenocarbonyl derivatives where one of the CO ligands has been replaced by a CS or CSe ligand shows an increase in carbonyl bond order in the latter complexes [2,4,9]. This observation indicates that the carbonyl groups receive less electron density from the metal, illustrating that the CS

and CSe groups are capable of accepting more electron density from the metal than is CO. Good correlations between carbonyl stretching force constants and the carbonyl resonances in the ^{13}C NMR spectra of (η -Arene)M(CO)₂(CX) (X = S, Se) complexes have been reported [5,8,9]. The incorporation of a CX ligand into a complex results in an upfield shift of the carbonyl resonances, indicative of a decrease in the donation of electron density from the metal to the CO groups.

In view of the differences between the CX and CO ligands, the chemical behaviour of thio- and selenocarbonyl complexes and their carbonyl analogues would also be expected to differ. The existing data on the thermal reactivity of Group VIB metal thio- and selenocarbonyl complexes are discussed below and are schematically reviewed in Figures 2.1 and 2.2.

Treatment of Cr(CO)₅(CS) in refluxing toluene or of W(CO)₅(CS) in refluxing xylene with Ph₃P [Eq. 2.1] yields both cis and trans isomers of M(CO)₄(CS)(Ph₃P).

(2.1)

cis

trans

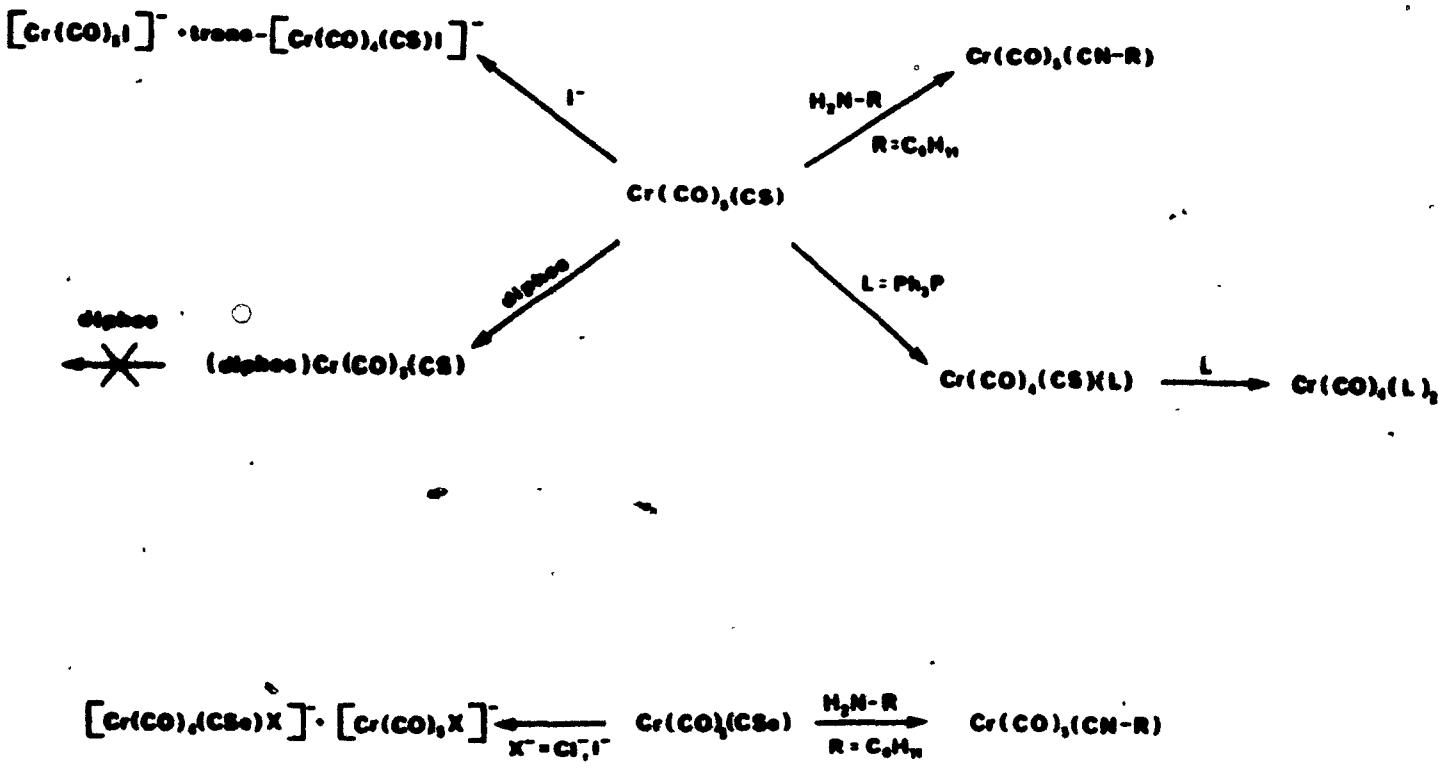

Figure 2.1. Thermal reactivities of $\text{Cr}(\text{CO})_5(\text{CS})$ and $\text{Cr}(\text{CO})_5(\text{CSe})$.

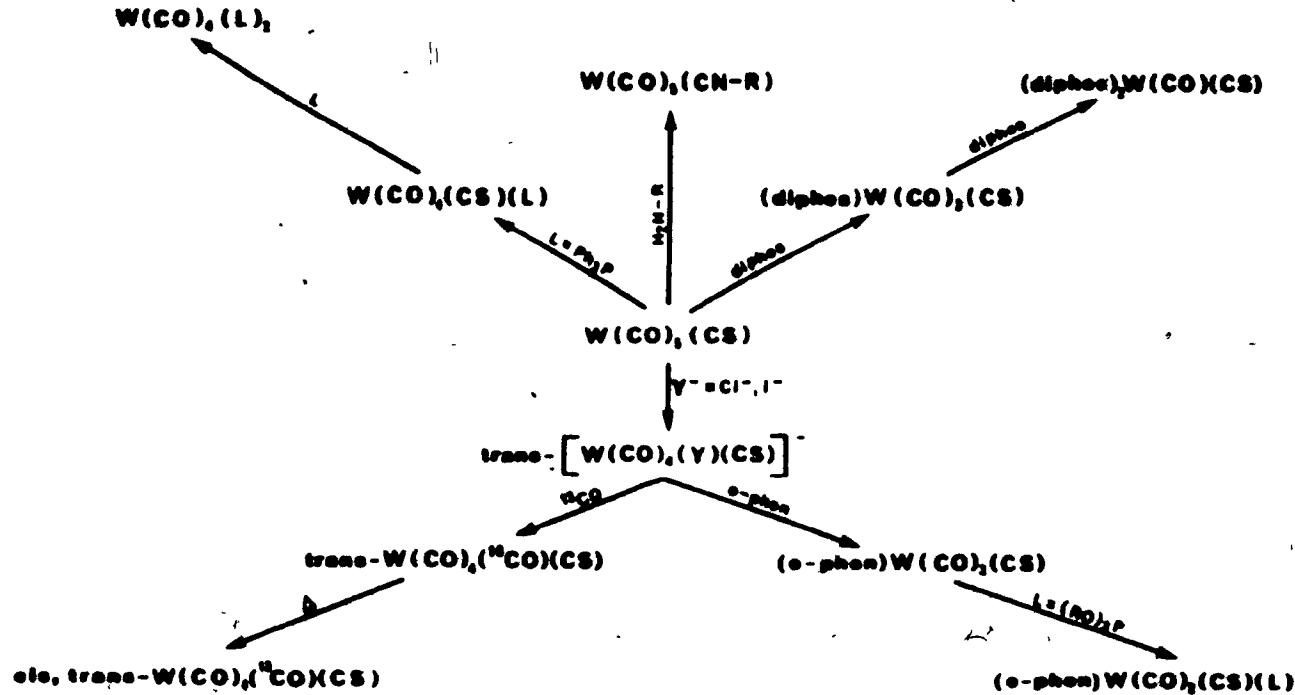

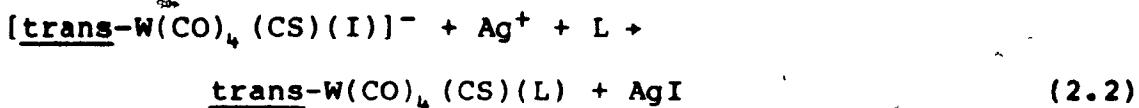

Figure 2.2. Thermal reactivities of $\text{W}(\text{CO})_5(\text{CS})$.

These isomers were inseparable by either column chromatography or fractional distillation [17]. Synthesis of pure trans-W(CO)₄(CS)(Ph₃P) by a different route (vide infra; Eq. 2.2) and subsequent heating at 105°C results in its isomerization to an equilibrium mixture of cis and trans with a much higher proportion of trans (cis:trans ~ 0.7:1) isomer than predicted on the basis of a statistical distribution of the phosphine (cis:trans 4:1), demonstrating that the configuration in which the CS ligand is trans to a weak π-acceptor such as Ph₃P rather than trans to CO is favoured [18]. Investigations [19] using stereospecifically ¹³CO-labelled trans-W(CO)₄(¹³CO)(CS) revealed that this complex undergoes intramolecular isomerization to form cis- and trans-W(CO)₄(¹³CO)(CS) isomers in both decalin solution and the gas phase.

Further attempts to displace a second CO with another phosphine yielded M(CO)₄(Ph₃P)₂ as the major product, as well as spectroscopic amounts of M(CO)₃(CS)(Ph₃P)₂, which was not isolated [17]. However, the bidentate ligand ethylenebis(diphenylphosphine) (diphos) was found to react with M(CO)₅(CS) (M = Cr, W) to yield one product [17], M(CO)₃(CS)(diphos), which was assigned a mer geometry on the basis of its IR spectrum; two carbonyl stretching modes were observed - a weak band at higher energy, attributed to the a' stretching mode of the two trans carbonyls, and a strong

band at lower frequency assigned to the a'' mode. The third band expected for this structure was presumed hidden under the strong lower-frequency band. Extended reaction of $W(CO)_5(CS)$ in excess diphos at very high temperatures yielded $W(CO)(CS)(diphos)_2$. However, no substitution beyond a single diphos ligand was observed for chromium [17]. Reactions of $W(CO)_5(CS)$ with other bidentate ligands containing nitrogen, such as 2,2'-bipyridine (bpy) or o-phenanthroline (o-phen), yielded no thiocarbonyl-containing products, giving only $W(CO)_4(bpy)$ and $W(CO)_4(\text{o-phen})$, respectively [17]. Reaction with pyridine (py) produced large amounts of $W(CO)_5(py)$ [17]. $Cr(CO)_5(CX)$ ($X = S, Se$) reacts with tetrabutylammonium halides to give a mixture of $[Cr(CO)_5(Y)]^-$ and trans- $[Cr(CO)_4(CX)(Y)]^-$ in a ratio of 2/3 for $X = S$ and $Y^- = I^-, Cl^-$ [5], while for $X = Se$ a 5/4 mixture is obtained for $Y^- = Cl^-$ and a 3/1 mixture for $Y^- = I^-$ [5,20]. In order to establish if $[Cr(CO)_5(Y)]^-$ was produced by thermal decomposition of the trans- $[Cr(CO)_4(CX)(Y)]^-$ ion, thermal decomposition of a $[Cr(CO)_5(Y)]^-/\text{trans}-[Cr(CO)_4-(CX)(Y)]^-$ mixture was monitored by IR spectroscopy; no increase in the intensities of the $\nu(CO)$ bands due to the $[Cr(CO)_5(Y)]^-$ ion was observed [20]. On the other hand, $W(CO)_5(CS)$ reacts with tetrabutylammonium halides in a coordinating solvent (e.g., acetone, THF) to produce only one product [17], trans- $[W(CO)_4(CS)(Y)]^-$ ($Y^- = Cl^-, Br^-, I^-$).

The iodide complex undergoes halide abstraction and ligand substitution forming exclusively the trans product according to Eq. 2.2 [17].

Halide abstraction and subsequent coordination of bipy or o-phen in the presence of a coordinating solvent yields mer-W(CO)₃(CS)(bpy) or mer-W(CO)₃(CS)(o-phen), respectively [21]. These products were inaccessible through direct reaction of the bidentate ligand with W(CO)₅(CS).

It should be mentioned that M(CO)₅(CX) (X = S, Se) complexes exhibit other types of thermal reactivity, in addition to ligand substitution. Both chromium and tungsten thiocarbonyls as well as the chromium selenocarbonyl derivative undergo reactions with primary amines to produce M(CO)₅(CNR) (R = alkyl group) [20,22]. W(CO)₅(CS) has also been found [22] to react with secondary amines forming thioformamide complexes, W(CO)₅(S=C(H)NR₂). Kinetic investigations of the reaction of W(CO)₅(CS) with primary amines revealed a second-order dependence on amine concentration and a first-order dependence on the concentration of the thiocarbonyl complex [22]. The mechanism proposed on the basis of these data involves attack of a hydrogen-bonded

amine molecule, RHN-H...NH₂R, at the carbon of the thiocarbonyl ligand. Thus a second amine molecule acts as a catalyst, presumably by increasing the nucleophilicity of the attacking amine [22]. The reaction of cis- and trans-W(CO)₄(CS)(Ph₃P) with primary amines was found to be much slower than that of W(CO)₅(CS), with the cis isomer reacting faster than the trans [22]. The low reactivity of trans-W(CO)₄(CS)(Ph₃P) [approx. 20,000 times slower than W(CO)₅(CS)] has been attributed to increased electron density at the thiocarbonyl carbon due to the trans Ph₃P ligand, rendering attack by a nucleophile less favourable.

The kinetics of carbonyl substitution in W(CO)₅(CS) by Ph₃P were studied [17] to gain quantitative information about the reactivity of this complex compared to that of W(CO)₆. The rate was found to have a ligand-independent term and a ligand-dependent term as shown in Eq. 2.3.

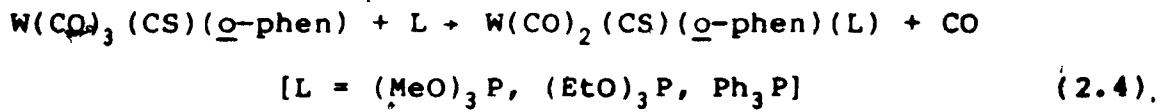

$$\underline{\text{rate}} = k_1 [\text{W}(\text{CO})_5(\text{CS})] + k_2 [\text{W}(\text{CO})_5(\text{CS})][\text{Ph}_3\text{P}] \quad (2.3)$$

This is analogous to the accepted mechanism for CO substitution in W(CO)₆ [23]. Comparison of k₁ and k₂ for the thiocarbonyl complex with values obtained for the reaction of W(CO)₆ with Ph₃P reveals that the dissociative mechanism is approximately 75 times faster in W(CO)₅(CS)

while the associative (k_2) route is 250 times faster [17]. Another kinetic study [17] involving the associative reaction of $W(CO)_5(CS)$ with I^- showed that $W(CO)_5(CS)$ reacts more than 1000 times faster with I^- than does $W(CO)_6$ under the same conditions.

The reaction of $\text{trans}-W(CO)_4(^{13}\text{CO})(CS)$ with I^- revealed that the trans CO is lost with high specificity [19]. The mechanism was postulated to involve attack by I^- at the metal accompanied by dissociation of the trans CO. Alternatively, the I^- may attack the C atom of the trans CO; subsequent rearrangement and loss of the trans CO would give the observed product. These two possibilities could not be distinguished on the basis of the kinetic data available [19].

A kinetic study of carbonyl dissociation from $W(CO)_3-$ (CS) (*o*-phen) has also been reported [Eq. 2.4] [21].

The rate of the reaction follows a general two-term rate expression [Eq. 2.5] in which $k_{\text{obsd}} = k_1 + k_2[L]$ under pseudo-first-order conditions.

$$\text{Rate} = k_1 [W(CO)_3(CS)(\underline{o\text{-phen}})] + k_2 [W(CO)_3(CS)(\underline{o\text{-phen}})][L] \quad (2.5)$$

At higher temperatures, the k_1 term predominates and k_{obsd} is independent of the concentration and the nature of the ligand [21]. At lower temperatures the rate shows a small but significant dependence on ligand concentration. A direct comparison of the rates of the dissociative pathway for the thiocarbonyl complex and $W(CO)_4(\underline{o\text{-phen}})$, made by extrapolating the rate constant for the thiocarbonyl reaction to the temperature at which the reaction of $W(CO)_4(\underline{o\text{-phen}})$ was studied [24], yields a k_1 value approximately 140 times faster for CO dissociation from the thiocarbonyl complex than from the carbonyl analogue.

The only kinetic data obtained for the reaction of Group VI B metal thiocarbonyl complexes have been those presented above for $W(CO)_3(CS)$ and its derivatives. These data have illustrated the difference between carbonyl and thiocarbonyl reactivity. The CS ligand, being a stronger π -acceptor than CO, limits the electron density available at the metal for π -backbonding to the carbonyl groups, especially the carbonyl trans to it. The CS ligand thus activates the complex to substitution by weakening the M-CO bonds (predominantly the trans M-CO bond), thereby reducing the activation energy and enhancing the rate of CO dissociation [17].

A striking example of labilization of ligands other than CO resulting from the presence of a thiocarbonyl or a selenocarbonyl ligand in a complex is the arene labilization observed for (η -Arene)Cr(CO)₂(CX) (X = S, Se) [2,5,20]. Cr(CO)₅(CS) can be prepared by heating (mbz)Cr(CO)₂(CS) under CO pressure (10 atm) at 65°C for 5 h. These conditions are much milder than those required to produce Cr(CO)₆ from (mbz)Cr(CO)₃ (65°C, 20 atm CO, 6 days). In addition, the lability of the arene in (η -Arene)Cr(CO)₂(CSe) complexes is even more pronounced; (mbz)Cr(CO)₂(CSe) reacts with CO at 10 atm pressure in 1 h at 65°C to yield Cr(CO)₅(CSe).

Apart from the reactions with CO mentioned above, the thermal reactivity of (η -Arene)Cr(CO)₂(CX) (X = S, Se) has not been previously investigated. In the present chapter, reactions of these complexes involving arene displacement by trialkyl- and triarylphosphites and selected tridentate phosphine ligands will be described.

2.2 Experimental

All synthetic reactions were performed under an atmosphere of prepurified nitrogen. All solvents were freshly distilled over sodium strips under nitrogen prior to use with the exception of 1,2-dichloroethane and CS₂ which were distilled over calcium chloride and molecular sieves, respectively.

Trialkyl- and triarylphosphites were purchased from Aldrich Chemical Co., with the exception of $(C_6H_{11}O)_3P$ which was obtained from Strem Chemicals. Carbon diselenide, chromium hexacarbonyl and the tridentate ligands bis(2-diphenylphosphinoethyl)phenylphosphine (triphos), 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos-U) and 1,1,1-tris(diphenylphosphino)methane (tripod) were purchased from Strem. $(CH_3)_2Cr(CO)_3$ was either prepared by the literature method [25], or purchased from Strem.

FT-IR spectra were recorded on a Nicolet 6000 spectrometer (32 scans, 1 cm^{-1} resolution). Proton, ^{13}C and ^{31}P NMR spectra were measured on a Varian XL-200 or XL-300 spectrometer equipped with a broad-band probe. The chemical shifts reported here are relative to TMS (^1H and ^{13}C) and 85% H_3PO_4 (^{31}P).

Chromatographic separation of the products was performed by column chromatography (silica gel 60-200 mesh) under N_2 atmosphere or on preparative TLC plates (1 mm) prepared from a slurry of 80 g silica gel G (Macherey, Nagel & Co., 516 Durn, West Germany) and 180 ml water. The plates were activated prior to use by heating them at 110°C for 1 h.

2.2.1 Synthesis of (η -Arene)Cr(CO)₃

All (η -Arene)Cr(CO)₃ complexes were prepared according to a literature method [26], outlined below for (o-xyl)Cr(CO)₃. A 1-liter three-necked flask fitted with a reflux condenser and a cold finger was used. The addition of the cold finger is a new modification that has been found to eliminate the possibility of the condenser blocking with the easily sublimable starting material Cr(CO)₆.

Preparation of (o-xyl)Cr(CO)₃. Cr(CO)₆ (9.6 g), o-xylene (50 ml), THF (35 ml) and Bu₂O (230 ml) were added under a stream of N₂ to the 1-liter flask. The mixture was heated slowly (at the reflux temperature of THF) overnight with magnetic stirring, allowing the Cr(CO)₆ to dissolve. The temperature was then increased to the reflux temperature of Bu₂O for 2 days. An IR spectrum was measured to confirm the complete disappearance of Cr(CO)₆ [ν (CO) 1980 cm⁻¹]. The flask was then cooled and the reaction mixture filtered in air using a sintered glass funnel (medium porosity) to remove any decomposition products. The solvent was then evaporated on a rotary evaporator using a liquid nitrogen trap to collect the solvent. Bright yellow crystals were obtained (yield 9.4 g, 88%).

2.2.2 Synthesis of (η -Arene)Cr(CO)₂(CS)

The procedure for arene chromium thiocarbonyl synthesis was identical to that in the literature [27]. However since a large amount of (bz)Cr(CO)₂(CS) was needed for kinetic studies, the procedure was modified to allow bulk synthesis of this complex.

(bz)Cr(CO)₃ (6 g) was dissolved in 1.8 liter of benzene and 300 ml of cis-cyclooctene under N₂ in a 3-liter flask. A stainless steel transfer needle (18 gauge) was then used to transfer 700 ml of the solution to a quartz reactor [27]. The solution was then irradiated with a 450-W quartz mercury vapour lamp for 60 min. The reaction was monitored by the increase in the IR carbonyl peaks of (bz)Cr(CO)₂(C₈H₁₄) [ν (CO) 1900, 1850 cm⁻¹]. The irradiated solution was then transferred to another 3-liter flask. After two additional cycles of this procedure, 500 ml of CS₂ were added to the irradiated solution. The workup at this point was identical to the established method [27].

2.2.3 Synthesis of (η -Arene)Cr(CO)₂(CSe)

(η -Arene)Cr(CO)₂(CSe) complexes were synthesized according to the previously reported procedure [28]; attempts to scale up the reaction resulted in poor yields.

2.2.4 Synthesis of Cr(CO)₂(CX)[(RO)₃P]₃ (X = S, Se), (R = Me, Et, n-Bu, Ph)

All Cr(CO)₂(CX)[(RO)₃P]₃ complexes were prepared according to the method outlined below for Cr(CO)₂-(CS)[(MeO)₃P]₃ and Cr(CO)₂(CSe)[(MeO)₃P]₃.

Preparation of Cr(CO)₂(CS)[(MeO)₃P]₃. (mbz)Cr(CO)₂(CS) (200 mg, 0.69 mmol) was dissolved in toluene (25 ml). (MeO)₃P (1.5 ml, 12.7 mmol) was added and the reaction mixture was heated for 12 h at 65°C under N₂. After allowing the solution to cool to room temperature, all volatile material was removed under reduced pressure on a rotary evaporator. The yellow solid remaining was purified by preparative TLC on silica gel plates (eluent: 1,2-dichloroethane). Yield 275 mg (75%). Anal. (Guelph Chemical Laboratories, Guelph, Ontario, Canada) Calcd. for C₁₂H₂₇O₁₁P₃Scr: C, 27.6; H, 5.19; P, 17.7. Found: C, 27.2; H, 5.15; P, 17.0. FT-IR (methylcyclohexane): ν (CO) 1976(w), 1899(vs) cm⁻¹; ν (CS) 1199(m) cm⁻¹. ¹H NMR (CD₂Cl₂): 3.40 (d, J = 11 Hz, 1), 3.72 ppm (d, J = 11 Hz, 2). ¹³C NMR (CD₂Cl₂): 224.2 (q, J = 22 Hz, 2CO), 336.5 ppm (td, J_t = 30 Hz, J_d = 6 Hz, CS). ³¹P NMR (C₆D₅CD₃): 181.2 (t, J = 65 Hz, 1), 188.6 ppm (d, J = 65 Hz, 2). Crystals were grown in pentane at -20°C.

Preparation of Cr(CO)₂(CSe)[(MeO)₃P]₃. The same procedure as described above was utilized for the synthesis of Cr(CO)₂(CSe)[(MeO)₃P]₃ from (bz)Cr(CO)₂(CSe) (250 mg, 0.90 mmol) and (MeO)₃P (2.1 ml, 17.8 mmol). Purification by TLC as above gave a bright yellow solid. Yield 355 mg (69%).
Anal. (Guelph Chemical Laboratories, Guelph, Ontario, Canada) Calcd. for C₁₂H₂₇O₁₁P₃SeCr: C, 25.26; H, 4.74. Found: C, 25.09; H, 4.90. FT-IR (CS₂): ν(CO) 1980.1(w), 1902.8(vs) cm⁻¹; ν(CSe) 1018(m) cm⁻¹. ¹H NMR (C₆D₆): 3.37 (d, J = 10 Hz, 1), 3.81 ppm (d, J = 10 Hz, 2). ¹³C NMR (C₆D₆): 223.8 (q, J = 22 Hz, 2CO), 356.5 ppm (td, J_t = 29 Hz, J_d = 6 Hz, CSe). ³¹P NMR (C₆D₅CD₃): 177.5 (t, J = 65 Hz, 1), 184.9 ppm (d, J = 64 Hz, 2). Yellow crystals of Cr(CO)₂(CSe)[(MeO)₃P]₃ were obtained upon cooling a saturated pentane solution of the complex to -20°C.

2.2.5 Preparation of (triphos-U)Cr(CO)₂(CS)

Triphos-U [(Me)C(CH₂P(Ph)₂)₃] (985 mg, 1.58 mmol) and (bz)Cr(CO)₂(CS) (197 mg, 0.855 mmol) were dissolved under N₂ in 25 ml of toluene. The reaction was heated at 90°C overnight. The resulting solution was evaporated under reduced pressure, affording a yellow solid. The product was purified by TLC on silica gel plates using CS₂ as the moving phase. The yellow fraction was extracted with methylene chloride and evaporated to dryness. The solid obtained was

dissolved in a minimal amount of benzene and hexane was added slowly to precipitate bright yellow crystals. Yield 617 mg (93%). Anal. (Guelph Chemical Laboratories, Guelph, Ontario, Canada) Calcd. for $C_{44}H_{39}O_2P_3SCr$: C, 68.04; H, 5.02. Found: C, 67.87; H, 5.25. FT-IR (CH_2Cl_2): $\nu(CO)$ 1927.7(s), 1866.1(s) cm^{-1} ; $\nu(CS)$ 1190(m) cm^{-1} .

2.2.6 Preparation of (triphos)Cr(CO)₂(CS)

Triphos [($Ph_2PCH_2CH_2)_2PhP$] (1.02 g, 1.91 mmol) and (bz)Cr(CO)₂(CS) (203 mg, 0.88 mmol) were dissolved in 25 ml of toluene and heated at 95°C overnight while stirring under nitrogen. The workup was identical to the procedure described above for (triphos-U)Cr(CO)₂(CS). Attempts to separate the isomers of (triphos)Cr(CO)₂(CS) by TLC using various eluents (1,2-dichloroethane:hexane 3:1, benzene:CS₂ 2:1, ethyl acetate:petroleum ether 3:2) were unsuccessful. Yield 570 mg (94%). Anal. (Guelph Chemical Laboratories, Guelph, Ontario, Canada) Calcd. for $C_{37}H_{33}O_2P_3SCr$: C, 64.66; H, 4.85. Found: C, 64.24; H, 5.02. IR (CH_2Cl_2): $\nu(CO)$ 1924.0(s), 1860.9(s) cm^{-1} ; $\nu(CS)$ 1191.4(m) cm^{-1} . ³¹P NMR ($C_6D_5CD_3$): isomers A and A* 67.4 (dd, I = 1), 79.8 (dd, I = 1), 107.5 ppm (dd, I = 1); isomer B 100.9 (t, I = 1), 71.9 ppm (d, I = 2).

2.2.7 Synthesis of $(L-L-L)Cr(CO)_2(CSe)$ ($L-L-L = \text{triphos-U}$,
 triphos)

These complexes were prepared in quantitative yield according to the methods outlined above for the corresponding thiocarbonyl derivatives.

2.2.8 Reaction of Tripod $[HC(P(Ph)_2)_3]$ with $(bz)Cr(CO)_2(CX)$ ($X = S, Se$)

583 mg (1.01 mmol) of tripod and an equimolar amount of $(bz)Cr(CO)_2(CX)$ were dissolved in 25 ml of benzene. Decomposition occurred upon heating the reaction mixture with no new peaks appearing in the carbonyl region of the IR spectrum.

2.2.9 Synthesis of $Cr(CO)_3[(RO)_3P]$, ($R = Me, Et, n\text{-}Bu, Ph$) and $(L-L-L)Cr(CO)_3$ ($L-L-L = \text{triphos and triphos-U}$)

The above complexes were prepared from $(cht)Cr(CO)_3$ by the same procedures as described above for the corresponding thio- and selenocarbonyl derivatives.

2.2.10 Attempted Synthesis of $(cht)Cr(CO)_2(CS)$ by Photolysis of $(cht)Cr(CO)_3$

$(cht)Cr(CO)_3$ (200 mg) was irradiated in 150 ml of toluene in the presence of excess cis-cyclooctene (50% by volume) under N_2 for periods ranging from 1 to 4 h using a

450-W quartz mercury vapour lamp. No changes in the $\nu(\text{CO})$ absorptions were observed in the FT-IR spectrum. Warming the solution during irradiation brought about decomposition.

2.2.11 Reaction of $\text{Cr}(\text{CO})_5(\text{CS})$ with Cycloheptatriene

$\text{Cr}(\text{CO})_5(\text{CS})$ (30 mg) (prepared according to Reference 20) was refluxed in neat cycloheptatriene (30 ml) under N_2 . No product formation was detected by FT-IR spectroscopy. In the presence of THF or acetonitrile (10% by volume) decomposition occurred.

2.2.12 Attempted Synthesis of $(\text{cht})\text{Cr}(\text{CO})_2(\text{CS})$ by Arene Exchange

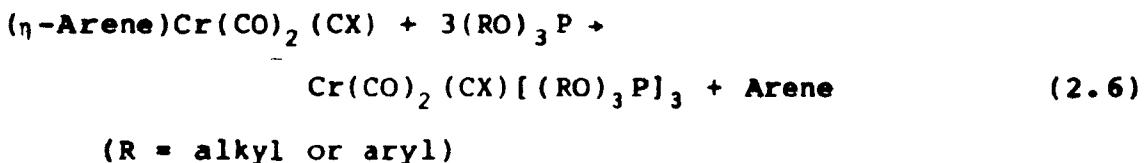

$(\text{mbz})\text{Cr}(\text{CO})_2(\text{CS})$ (30 mg) was dissolved in 10 ml of neat cycloheptatriene, or in cycloheptatriene containing 10% (by volume) THF or acetonitrile and heated at 65°C under N_2 for periods of 6-48 h. The progress of the reaction was monitored by difference FT-IR spectroscopy. In all cases, gradual decomposition was observed with no appearance of new $\nu(\text{CO})$ peaks in the IR spectrum.

2.3 Results and Discussion

Since the synthesis of the first (η -Arene) $\text{Cr}(\text{CO})_2(\text{CS})$ and (η -Arene) $\text{Cr}(\text{CO})_2(\text{CSe})$ complexes a decade ago, few chemi-

cal reactions have been reported for them. However, a variety of spectroscopic techniques have provided a clear indication of the bonding properties of the CS and CSe ligands. The synthetic investigations described here have probed further the chemical behaviour of arene chromium thio- and selenocarbonyl complexes. The thermal reactivities of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S, Se}$) complexes established in this study together with those reported in the literature are summarized in Figure 2.3.

The major reaction of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2\text{CX}$ complexes identified in this work, the kinetics of which will be the subject of Chapter 4, is the displacement of the arene by three tertiary phosphite ligands under relatively mild conditions:

The spectroscopic properties and the crystal and molecular structure of a typical product, $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$, are presented in this and the next section. Following this, the crystal structure of the analogous selenocarbonyl derivative will be described.

The $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$ complex is the first example

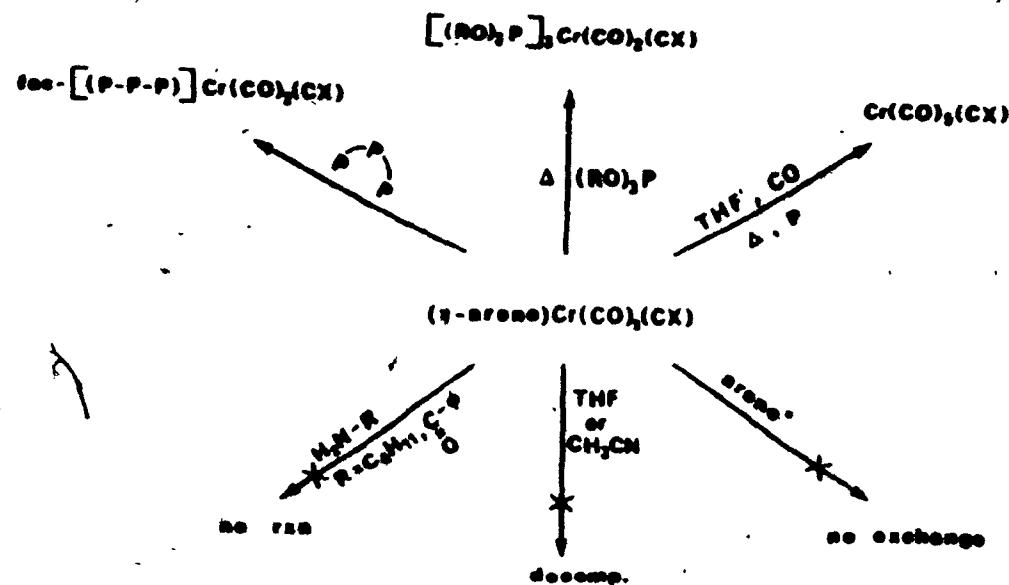

Figure 2.3. Thermal reactivities of $(\eta\text{-Arene})Cr(CO)_2(CX)$ ($X = S, Se$).

of a substituted Group VIB metal thiocarbonyl complex containing more than one monodentate ligand other than CO. Attempts to prepare such complexes from $\text{Cr}(\text{CO})_5(\text{CS})$ by thermal replacement of the CO groups have only resulted in the loss of the CS ligand following the first substitution step, i.e., yielding first $\text{Cr}(\text{CO})_4(\text{CS})\text{L}$ and then $\text{Cr}(\text{CO})_4\text{L}_2$ [17]. Thus, arene substitution provides the first entry into multi-substituted complexes of the type $\text{Cr}(\text{CO})_2(\text{CS})\text{L}_3$.

Arene displacement in $(\eta\text{-Arene})\text{M}(\text{CO})_3$ complexes affords fac- $\text{M}(\text{CO})_3\text{L}_3$ ($\text{M} = \text{Cr}$, $\text{L} = \text{CH}_3\text{CN}$ [29]; $\text{M} = \text{Mo}$, $\text{L} = (\text{MeO})_3\text{P}$, Cl_3P , Ph_2ClP , $n\text{-Bu}_3\text{P}$ [30,31]; $\text{M} = \text{W}$, $\text{L} = (\text{MeO})_3\text{P}$ [32]). fac- $\text{M}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ ($\text{M} = \text{Cr}$, Mo , W) has also been synthesized by the substitution of cycloheptatriene in $(\text{cht})\text{M}(\text{CO})_3$ by $(\text{MeO})_3\text{P}$ [25]. The fac stereochemistry of the products was established by the appearance of two strong $\nu(\text{CO})$ peaks in the IR spectra, in accord with the C_{3v} local symmetry of the $\text{M}(\text{CO})_3$ moiety [$\Gamma(\text{CO}) = a_1 + e$]. In the present work, as well as in other studies [25], it has been observed that cycloheptatriene displacement from $(\text{cht})\text{Cr}(\text{CO})_3$ by $(\text{MeO})_3\text{P}$ in refluxing methylcyclohexane yields a mixture of fac- and mer- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$. Similar mixtures are obtained from the reactions of $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ complexes with monodentate ligands at high temperatures, as evidenced by the appearance of a third $\nu(\text{CO})$ band in the IR spectra and the splitting patterns in the ^{31}P NMR spectra of the products [33].

While the reactions of the tricarbonyl complexes described above give predominantly the fac isomer under the conditions employed in this work, the $\nu(\text{CO})$ region in the FT-IR spectrum of $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$ with one very strong and one very weak band being observed is clearly at variance with the intensity pattern expected for the fac isomer. The spectrum of the latter should most likely resemble that of fac- $\text{Cr}(\text{CO})_3\text{L}_3$ with two strong peaks of comparable intensity. The FT-IR spectrum of the crude product of this reaction, prior to TLC purification, exhibits an additional peak in the CO stretching region at 1961 cm^{-1} of weak intensity ($\sim 10\%$ of that of the 1899 cm^{-1} peak) (Figure 2.4). It will be shown below that this peak can be assigned to fac- $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$.

The very low intensity of the 1976 cm^{-1} peak of the major product is immediately suggestive of the mer geometry (mer I, Figure 2.5) in which the two CO groups are trans to each other. The mer stereochemistry is further indicated by the similarity of the ^{31}P NMR spectrum to that of mer- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ in $\text{C}_6\text{D}_5\text{CD}_3$ solution (Table 2.10), even down to the $^{2}\text{J}_{^{31}\text{P}}{}^{31}\text{P}$ couplings (64 Hz). The solitary ^{13}C resonance for the CO groups is evidence of the absence of mer II and its appearance as a quartet is in complete agreement with the splitting pattern expected for mer I provided that the two different tertiary phosphite environments are

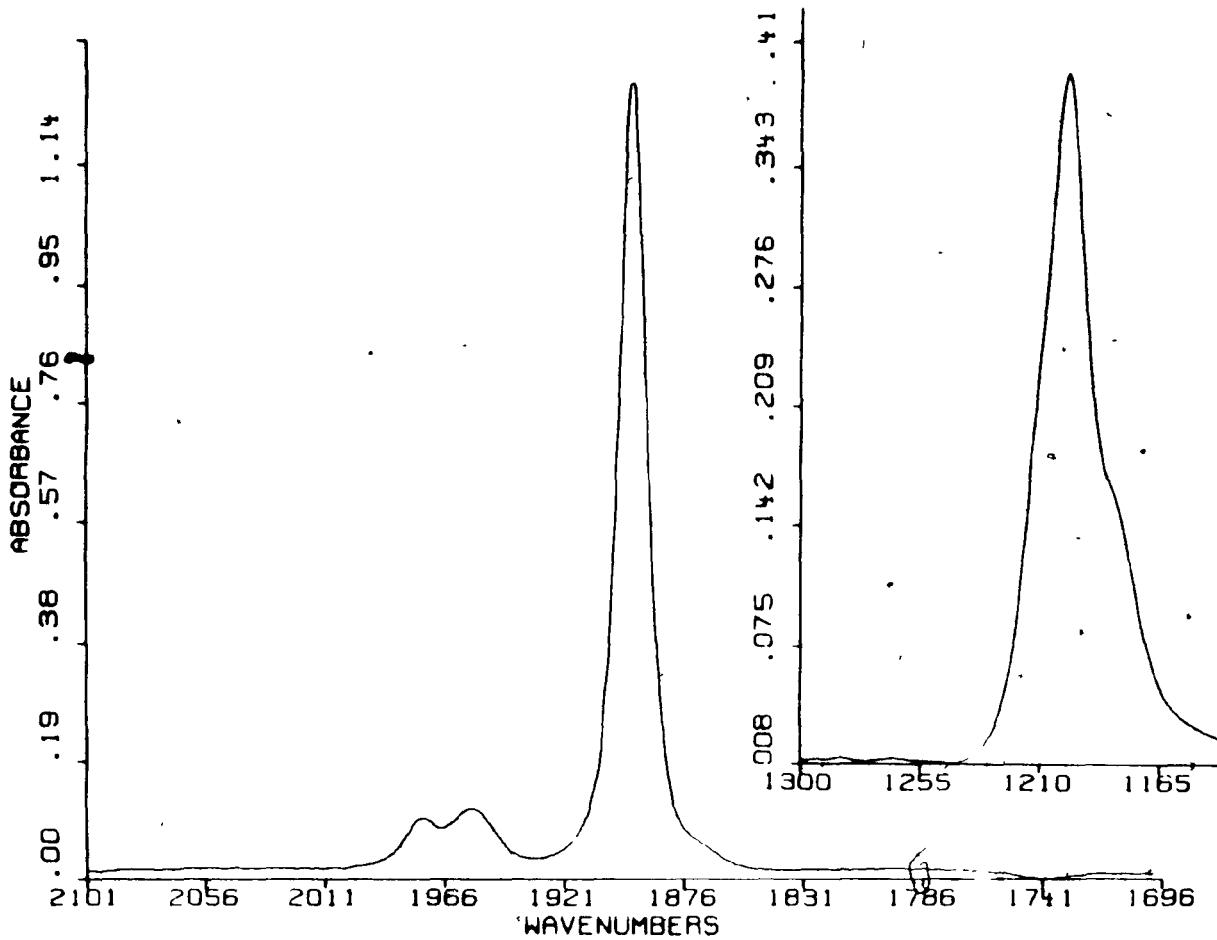

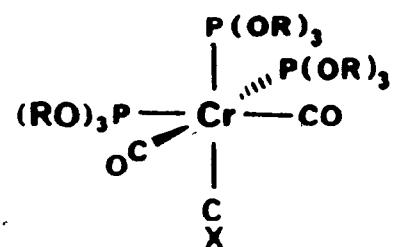

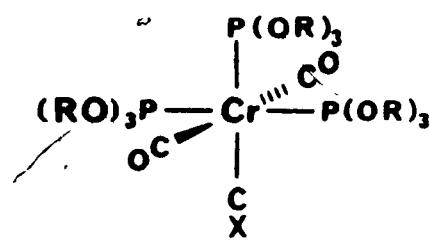

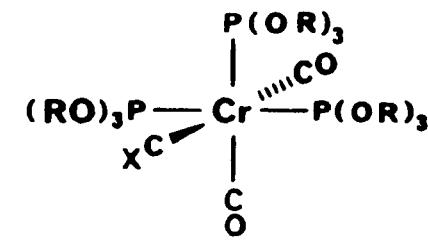

Figure 2.4. The $\nu(\text{CO})$ region of the FT-IR spectrum (in methylcyclohexane) of the crude product of the reaction of (*mbz*) $\text{Cr}(\text{CO})_2(\text{CS})$ with $(\text{MeO})_3\text{P}$. Inset: $\nu(\text{CS})$ region.

X = S, Se

Figure 2.5. The three possible isomers of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$).

sufficiently similar to afford comparable $^{2J}_{^{13}\text{C}^{31}\text{P}}$ values. The observed coupling constant (22 Hz) is very close to the $^{2J}_{^{13}\text{C}^{31}\text{P}}$ value reported for $\text{Cr}(\text{CO})_5[(\text{MeO})_3\text{P}]$ and trans- $\text{Cr}(\text{CO})_4[(\text{MeO})_3\text{P}]_2$ (21 Hz) [34]. The ^{13}CS resonance appears as a doublet, due to coupling with the trans ^{31}P nucleus, split into a triplet by the other two equivalent ^{31}P nuclei, again in accord with the predictions for mer I.

As mentioned above, the CO stretching region of the IR spectrum of the crude product obtained in the synthesis of $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$ contains, in addition to the peaks of mer- $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$, a weak peak at 1961 cm^{-1} . Subtraction of the spectrum of the pure mer product from this spectrum reveals a second peak at 1899 cm^{-1} of comparable intensity to that at 1961 cm^{-1} , as well as a peak in the $\nu(\text{CS})$ region at 1199 cm^{-1} . These data indicate that some quantity of either the fac or mer II isomer is present in the crude product. Further examination of the crude product using ^{13}C and ^{31}P NMR spectroscopy provided definitive evidence that the minor component present is fac- $\text{Cr}(\text{CO})_2(\text{CS})-[(\text{MeO})_3\text{P}]_3$. In addition to the peaks attributable to the mer I isomer, the ^{13}C NMR spectrum exhibits a single ^{13}CO resonance ($\delta = 226.3 \text{ ppm}$) split into a doublet of triplets and a ^{13}CS resonance ($\delta = 335.3 \text{ ppm}$) also split into a doublet of triplets. It is well established [8,34] that chalcocarbonyl resonances exhibit a downfield shift when

they are trans to a stronger σ -donor or a weaker π -acceptor than CO. On this basis the mer II isomer would be expected to exhibit a thiocarbonyl resonance at higher field than observed for the mer I isomer and two distinct carbonyl resonances, one at higher field than that of the mer I for the CO trans to the CS ligand, and the other at lower field for the CO trans to the phosphite group. Therefore, the ^{13}C NMR data are inconsistent with the identification of the minor product as the mer II isomer. For the fac isomer a single carbonyl resonance situated at lower field than that of the mer I isomer is expected, while the thiocarbonyl resonance is anticipated to appear at higher field on the basis that the CO groups should remove a larger share of the electron density donated by the tertiary phosphites to the metal in the fac isomer (CO trans to phosphite) than in the mer I (CO cis to phosphite) isomer. These predictions are completely in accord with the observed ^{13}C NMR spectra. The peaks in the ^{31}P NMR spectrum attributed to the minor product are also consistent with its identification as fac-Cr(CO)₂(CS)[(MeO)₃P]₃ with the two equivalent phosphorus nuclei (trans to CO) being split into a doublet by the third phosphorus (trans to CS) which in turn is split into a triplet. The fact that this doublet is at higher field than the doublet of the mer I is in line with the ^{31}P NMR observations made by Poilblanc and his coworkers that two trans

phosphorus ligands appear at lower field than a phosphorus ligand trans to CO for $M(CO)_3[(MeO)_3P]_3$ ($M = Cr, Mo, W$) [33].

The IR, ^{13}C NMR and ^{31}P NMR spectra of the crude and the purified product from the reaction of (n -Arene)- $Cr(CO)_2(CSe)$ with $(MeO)_3P$ exhibit the same intensity patterns as observed for the thiocarbonyl product. Thus, the characterization of both the mer I and fac isomers was established in a similar manner to the spectroscopic analysis described for $Cr(CO)_2(CS)[(MeO)_3P]_3$. The FT-IR spectrum of the crude $Cr(CO)_2(CSe)[(MeO)_3P]_3$ product is shown in Figure 2.6, while that of the yellow crystals obtained by TLC purification is displayed in Figure 2.7. The difference spectrum generated by subtraction of Figure 2.7 from Figure 2.6 is displayed in Figure 2.8, revealing the hidden $\nu(CO)$ peak of the fac isomer. The ^{13}C NMR spectrum (Figure 2.9) clearly shows the patterns expected for the mer I and fac isomers. The spectroscopic properties of $Cr(CO)_2(CX)-[(RO)_3P]_3$ ($X = O, S, Se; R = Me, Et, n-Bu, Ph$) derivatives will be discussed more fully in Section 2.3.3.

2.3.1 Crystal and Molecular Structure of $Cr(CO)_2(CS)-[(MeO)_3P]_3$

The mer stereochemistry (mer I) of the chromium thiocarbonyl derivative was confirmed by single-crystal X-ray

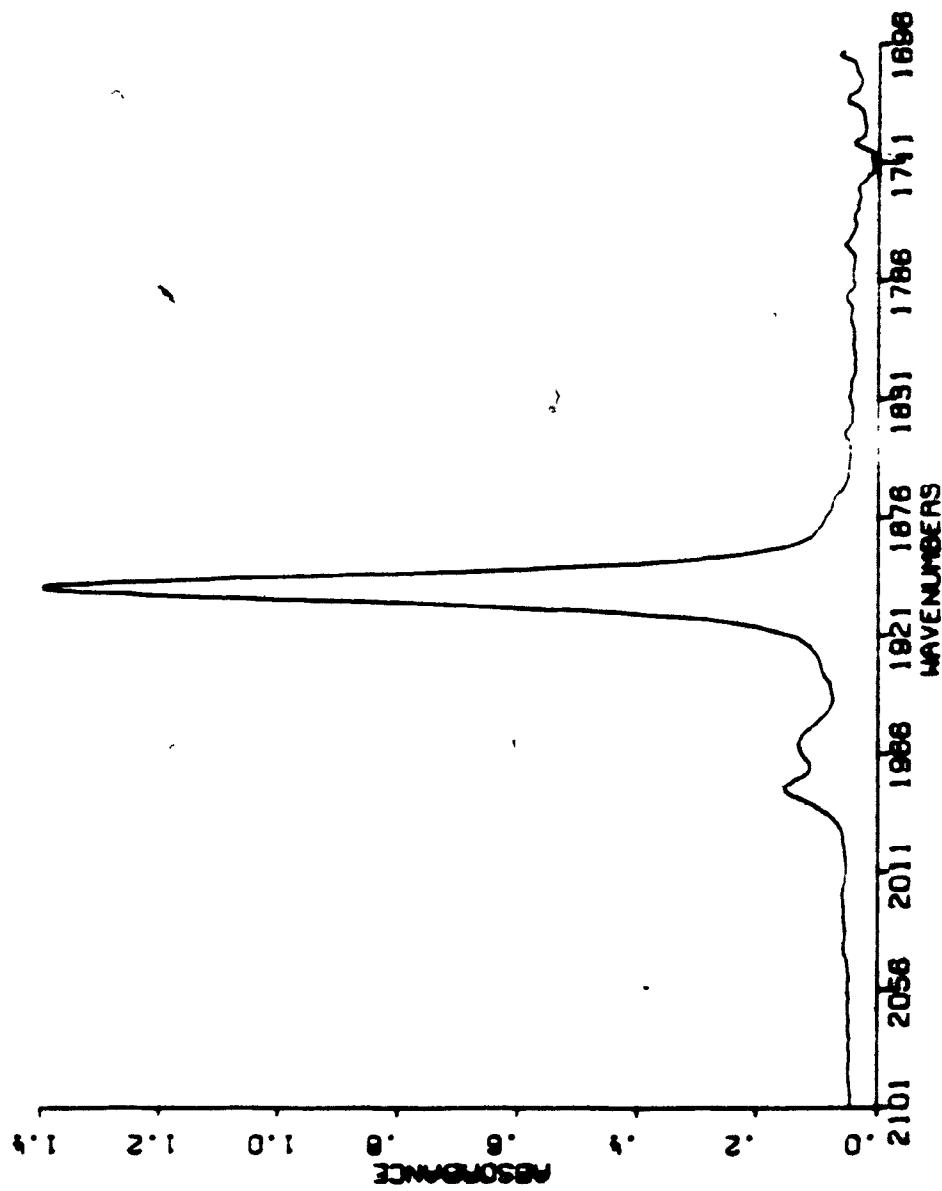

Figure 2.6. The $\nu(\text{CO})$ region of the IR-IR spectrum (in CS_2) of the crude product of the reaction of $(\text{nbs})\text{Cr}(\text{CO})_2(\text{CSe})$ with $(\text{MeO})_3\text{P}$.

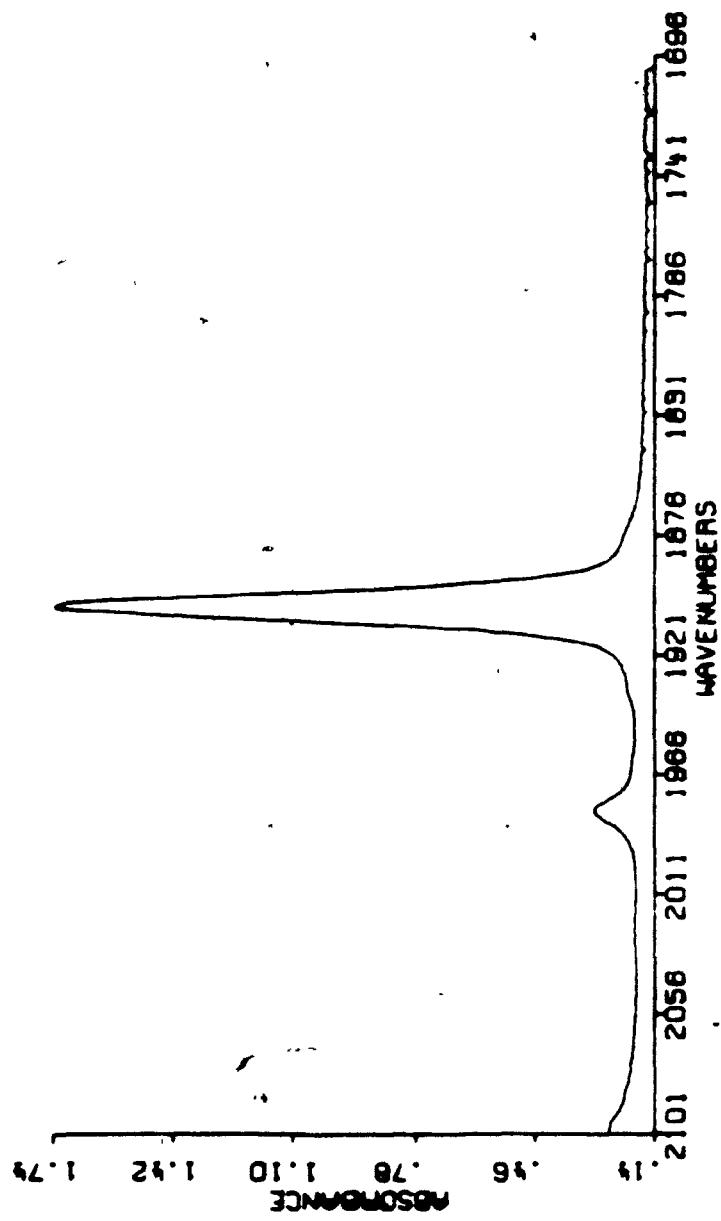

Figure 2.7. The $\nu(\text{CO})$ region of the FT-IR spectrum of the mer-I isomer of $\text{Cr}(\text{CO})_2(\text{CSe})(\text{MeO})_3\text{P}]_3$ in CS_2 .

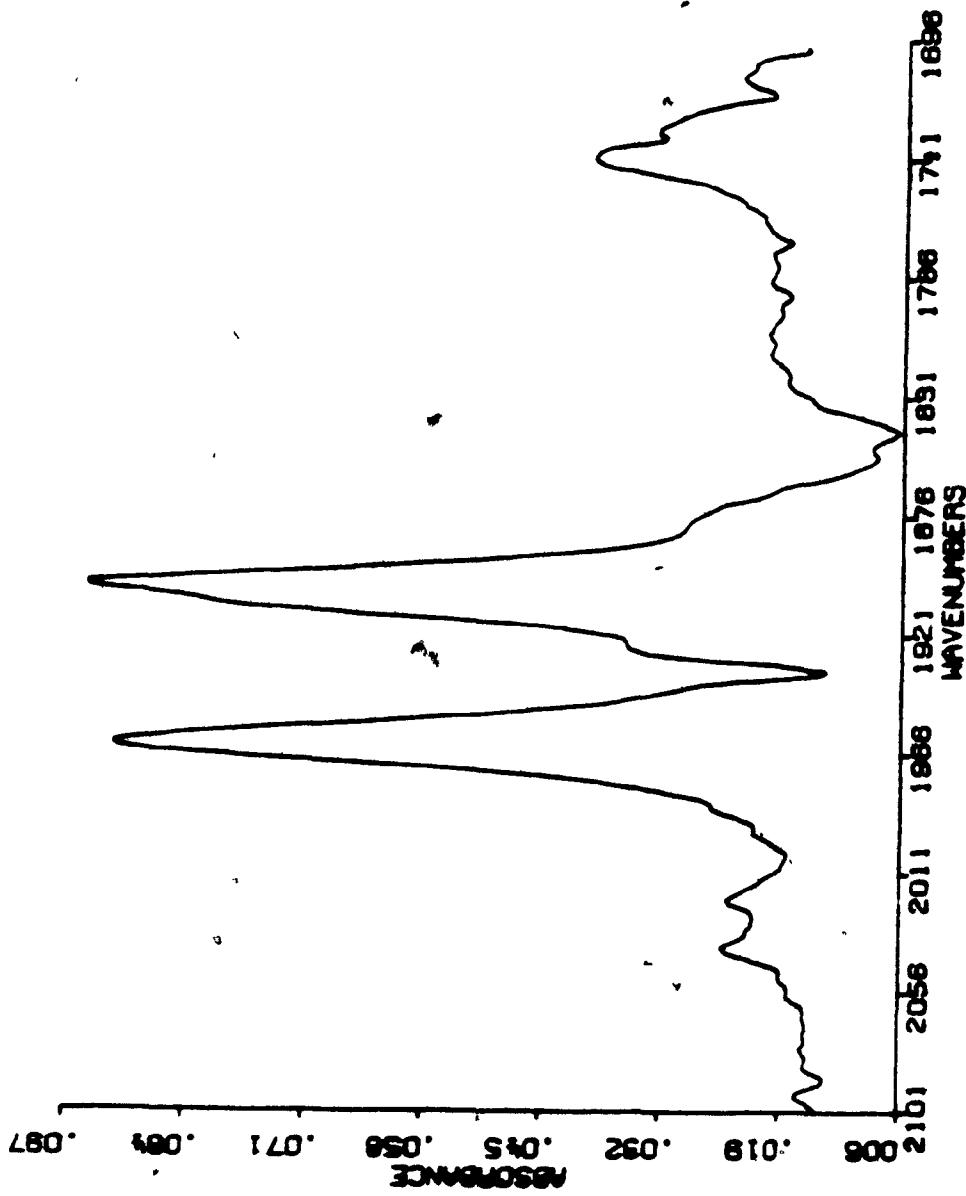

Figure 2.8. The $\nu(\text{CO})$ region of the FT-IR spectrum of $\text{Cr}(\text{CO})_2(\text{C}_8\text{H}_{11})(\text{MeO})_3\text{P}$ obtained by subtraction of the spectrum in Figure 2.7 from that in Figure 2.6.

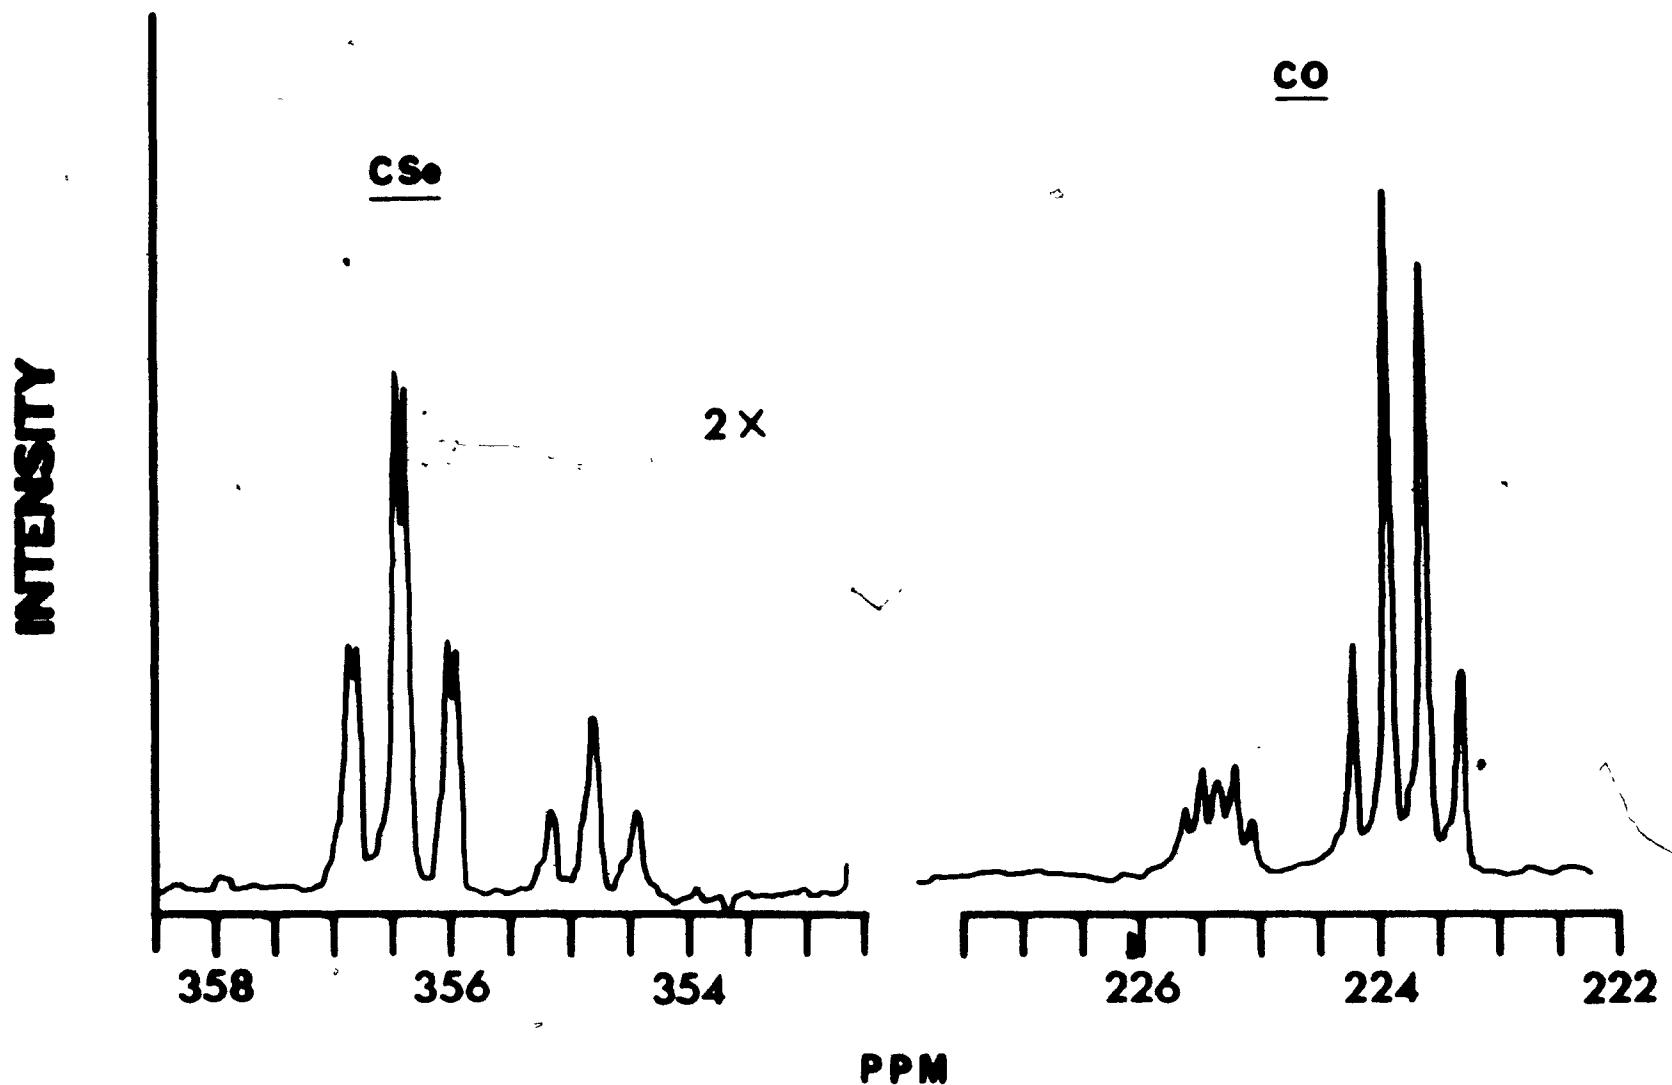

Figure 2.9. The chalcocarbonyl resonances in the ^{13}C NMR spectrum (in C_6D_6) of a mixture of the fac and mer I isomers of $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$. Conditions: obtained on a Varian XL-300 FT spectrometer operating at 75.43 MHz; ^1H -decoupled; sweep width = 30,200 Hz; offset = 7,100 Hz; flip angle = 20° ; repetition time = 0.6 s; number of scans = 2,624. Sample contained 0.1 M $\text{Cr}(\text{acac})_3$.

diffraction (see Appendix A for crystal parameters, final positional parameters and structure factors). The resulting perspective diagram including the labelling scheme is shown in Figure 2.10. The arrangement of the ligands around the central Cr(0) atom is slightly distorted from idealized octahedral geometry (see Table 2.1 for the interatomic angles). The OC-Cr-CO angle is $175.2(4)^\circ$, while the trans phosphorus atoms are bent away from P(2) with P(1)-Cr-P(3) = $174.0(1)^\circ$, presumably to minimize steric interactions between the three $(\text{MeO})_3\text{P}$ groups.

The interatomic distances are given in Table 2.2. The trans Cr-P bond lengths are equal within experimental error [mean value = $2.262(3)$ Å], while the Cr-P bond trans to CS is appreciably longer [$2.346(3)$ Å], i.e., an increase of $0.084(3)$ Å. This is attributed to the strong electron-withdrawing capacity of the CS ligand, leading to less π -back-donation from the metal to the phosphite and thus to a weakening (and lengthening) of the trans Cr-P bond.

A comparison of the Cr-C(S) and C-S bond lengths reported here with those in related metal thiocarbonyl complexes containing terminal CS linkages [35] reveals that these distances are among the longest C-S and shortest Cr-C(S) distances known. This effect is also reflected in the low value of the CS stretching mode (1199 cm^{-1}). The Cr-C(S) bond distance is significantly shorter than the mean Cr-C(O)

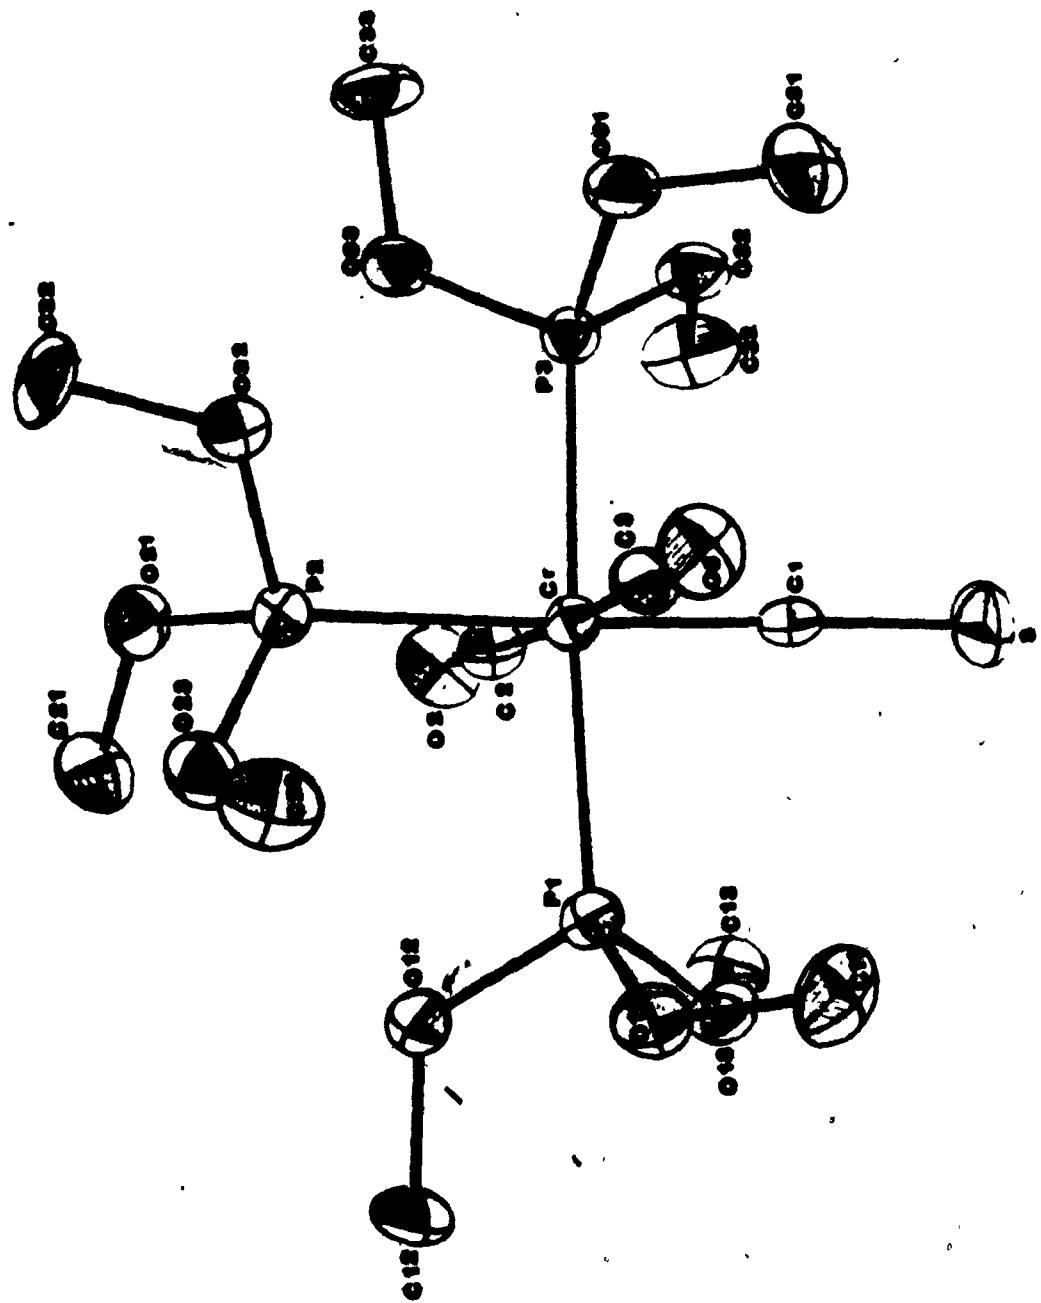

Figure 2.10. A perspective drawing of the mer I isomer of $\text{Cr}(\text{CO})_2(\text{C}_8)(\text{MeO})_3\text{P}_3$, with hydrogen atoms omitted for clarity.

value [1.839(9) Å]. These different observations are attributed to the relatively large amount of electron density available for π -backbonding at the metal centre resulting from the presence of the three strongly σ -donating tertiary phosphite ligands.

Woodard *et al.* have reported a linear relationship between the CS stretching frequency and the C-S bond length in a series of terminal thiocarbonyl complexes [35]. Least-squares analysis of the currently available data given in Table 2.3 (excluding Fe(OEP)(CS)) yields a correlation coefficient of 0.99. Inclusion of Fe(OEP)(CS) reduces the correlation significantly ($r = 0.94$). This difference may be attributed to appreciable mixing of $\nu(\text{CS})$ with $\nu[\text{M}-\text{C}(\text{S})]$, as observed in analogous porphinato thiocarbonyl complexes [36].

2.3.2 Crystal and Molecular Structure of $\text{Cr}(\text{CO})_2(\text{CSe}) - [(\text{MeO})_3\text{P}]_3$

In this section, the crystal and molecular structure determined by a single-crystal X-ray diffraction study at 118 K of a typical selenocarbonyl product, $\text{Cr}(\text{CO})_2(\text{CSe}) - [(\text{MeO})_3\text{P}]_3$, of the reaction of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CSe})$ with trialkylphosphite is presented. These data confirm the mer-I configuration postulated on the basis of spectroscopic properties (FT-IR; ^{13}C , ^{31}P NMR) and the established struc-

thesis (in KBr pellet), and ^dfrom Reference 43.

ture of the thiocarbonyl analogue described in the previous section.

The final atomic coordinates are given in Appendix B (along with the crystal parameters and structure factors), while the bond angles and distances are listed in Tables 2.4 and 2.5, respectively. A perspective view of the structure indicating the atom labelling scheme used is shown in Figure 2.11. The coordination around the central Cr atom is essentially octahedral. The Cr-C-Se linkage is linear [176.9(2)°] with bond distances of Cr-C = 1.785(3) Å and C-Se = 1.750(3) Å. These values for the selenocarbonyl linkage are much more precise than those in the literature from the room temperature studies on $(mbz)Cr(CO)_2(CSe)$ (Cr-C-Se = 179.0(7)°, Cr-C = 1.79(1) Å, C-Se = 1.73(1) Å; [37]) and $RuCl_2(CO)(CSe)[(C_6H_5)_3P]_2$ (Ru-C-Se = 174(1)°, C-Se = 1.07(2) Å; [38]). The Cr-C(Se) distance in the present case is 0.108(1) Å shorter than the mean Cr-C(O) distance [1.893(3) Å] and the Cr-P distance for the $(MeO)_3P$ ligand trans to CSe is 0.091(1) Å longer than the mean Cr-P value [2.282(1) Å] for the other two $(MeO)_3P$ ligands. While these trends are identical to those observed for the thiocarbonyl analogue, the lengthening in the Cr-P bond trans to CSe is about 0.02 Å more than the corresponding lengthening for the thiocarbonyl complex suggesting that CSe is slightly better than CS in terms of electron-withdrawing capacity. A

similar very strong electron-withdrawing effect was found for CSe in $\text{RuCl}_2(\text{CO})(\text{CSe})[(\text{C}_6\text{H}_5)_3\text{P}]_2$ since the Ru-Cl distance trans to CSe is 2.480(5) Å, while the one trans to CO is 2.427(5) Å [38].

2.3.3 FT-IR and ^{31}P NMR Spectra of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{RO})_3\text{P}]_3$ ($\text{X} = \text{O, S, Se}$)

Arene displacement from $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S, Se}$) by tertiary phosphite ligands affords a variety of novel complexes of spectroscopic interest. The IR data for these complexes give added support as to the effectiveness of the thiocarbonyl group in decreasing the net electron density at a metal centre compared to CO in the analogous parent carbonyl complexes. This can be clearly seen from the increase in the mean IR wavenumber for the carbonyl groups in the thiocarbonyl complexes in Tables 2.6 and 2.7 resulting from the decreased back-donation of electron density from the metal to the π^* orbitals of the CO groups [1].

The number of known Group VIB metal selenocarbonyl complexes is quite limited and restricted to chromium for reasons discussed elsewhere [5]. The compounds listed in Tables 2.6-2.8 are the first examples of Group VIB metal complexes containing both phosphorus and selenocarbonyl ligands. These complexes triple the number of selenocarbonyls known for Group VIB metals and provide further sup-

port of the superiority of CSe to either CS or CO in depleting electron density from metals and other coordinated ligands, as indicated by the further increase in the stretching frequencies of the carbonyl ligands.

The poor correlation between the CX (X = S, Se) wave-number and the σ -donor/ π -acceptor properties of the other, bound ligands in chalcocarbonyl complexes has been reported by English et al. and attributed to appreciable mixing of the $\nu(CX)$ and $\nu[M-C(X)]$ modes [3,4]. However, a qualitative trend can be seen for the $\nu(CX)$ modes as the σ -donor/ π -acceptor properties of the ligands are varied. This trend appears to be sensitive to the net electron density at the metal rather than the stereochemistry of the ligands relative to each other. This is illustrated by comparison of the data for the fac and mer isomers in Tables 2.6 and 2.7. A similar result has also been noted by Woodard et al. for cis- and trans-W(CO)₄(CS)(L) derivatives [18].

To date, no ³¹P NMR data have been obtained for phosphorus-containing thio- or selenocarbonyl complexes of Group VIB metals. The ³¹P NMR spectra of M(CO)_{6-n}[_n(MeO)₃P]_n (M = Cr, Mo, W) complexes have been examined by Mathieu and co-workers (Table 2.9) [33]. From their investigation, they concluded that the nature of the central atom appears to be the major factor influencing the chemical shifts, and that the resonance of the phosphorus atom trans to a carbonyl

^aData from Reference 33.^bMost compounds were examined in benzene; chemical shifts are in ppm downfield from 85% H_3PO_4 .^cIn hexadecane solution.^dRemeasured in this study on a Varian XL-200 spectrometer.^eAssigned to the fac isomer in Reference 33.

group occurs at higher field than that for a phosphorus atom trans to another phosphorus. The latter trend was rationalized using Eq. 2.7 derived by Van Wazer and Letcher [39] where the ^{31}P chemical shift is treated as the summation of the σ -bond and π -bond contributions:

$$\delta - \delta_0 = \delta_\sigma + \delta_\pi \quad (2.7)$$

where δ_0 is a constant associated with the particular reference standard employed. Both the δ_σ and δ_π terms are negative and so an increase in the amount of metal $d\pi$ electron density transferred to the $d\pi$ orbitals or a decrease in the σ -donation from the phosphorus atom to the metal results in a shift of the ^{31}P resonance towards lower fields [33].

Table 2.10 summarizes the ^{31}P NMR data obtained for the $\text{Cr}(\text{CO})_2(\text{CX})[(\text{RO})_3\text{P}]_3$ ($X = \text{O}, \text{S}, \text{Se}; \text{R} = \text{Me}, \text{Et}, \text{n-Bu}, \text{Ph}$) complexes. A comparison of the ^{31}P resonance for the two phosphorus atoms trans to each other in the chalcocarbonyl triad reveals an upfield shift of about 7 ppm for the thio-carbonyl derivative and about 11.5 ppm for the selenocarbonyl derivative when compared to the tricarbonyl complex. These upfield shifts are indicative of a net decrease in electron density at the metal centre available for donation to the $d\pi$ orbitals of the phosphorus atoms and are consistent with the established order of π -acidity for chalcocar-

bonyl ligands ($\text{CSe} > \text{CS} > \text{CO}$). An increase in electron density donation from the phosphorus atoms to the relatively electron-deficient metal in the thio- and selenocarbonyl complexes may also contribute to the observed effect.

The signal for the phosphorus atom trans to the CX ligand is shifted upfield from that for the two trans phosphorus atoms. This resonance also is observed to shift to higher fields with increasing π - acidity of the CX ligand. The magnitudes of the shifts with variation in the CX ligand are comparable to those for the resonances of the two trans phosphorus atoms.

2.3.4 Reaction of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ with Tridentate Phosphine Ligands

Reaction of triphos-U with $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($X = \text{S, Se}$) yields novel complexes characterized as fac-(triphos-U) $\text{Cr}(\text{CO})_2(\text{CX})$ (Figure 2.12). The IR and ^{31}P NMR data are presented in Tables 2.8 and 2.11, respectively, together with data for the corresponding tricarbonyl complex. As expected, the mean IR $\nu(\text{CO})$ frequency shifts to higher wavenumber on descending the chalcocarbonyl triad. The ^{31}P NMR spectrum of the (triphos-U) $\text{Cr}(\text{CO})_3$ complex exhibits only one signal since the three phosphorus atoms are equivalent. In the case of (triphos-U) $\text{Cr}(\text{CO})_2(\text{CX})$ ($X = \text{S, Se}$), one phosphorus atom is trans to CX while two phosphorus atoms are

(triphos)Cr(CO) ₂ (CSe) (A)	10, 24	64.4(dd, I = 1) 76.9(dd, I = 1) 104.0(dd, I = 1)
(triphos)Cr(CO) ₂ (CSe) (B)	10	68.6(d, I = 2) 96.7(t, I = 1)

^aIn CD₂Cl₂ solution; chemical shifts (+0.1 ppm) are given with positive values downfield from 85% H₃PO₄.

trans to CO. The different environments result in a doublet and a triplet splitting pattern for these complexes where the ^{31}P signal trans to CX (triplet) is further upfield than the ^{31}P resonance (doublet) of the two phosphorus atoms trans to CO. Comparison of the ^{31}P resonance for $(\text{triphos-U})\text{Cr}(\text{CO})_3$ with that of the corresponding resonance of the phosphorus atoms trans to CO in $(\text{triphos-U})\text{Cr}(\text{CO})_2-(\text{CSe})$ indicates an upfield shift of 8 ppm in the selenocarbonyl complex. The phosphorus trans to CSe is approximately 5 ppm upfield from the other two phosphorus atoms trans to CO in the same complex.

Arene displacement by triphos from $(\eta\text{-Arene})\text{Cr}(\text{CO})_2-(\text{CX})$ ($\text{X} = \text{S, Se}$) affords three new interesting types of fac isomer (A, A* and B, where A* is an enantiomer of A) (Figure 2.13) that are not available to the parent tricarbonyl complex. The IR spectra (Figure 2.14) of the complexes in the carbonyl stretching region display only two strong absorptions with mean values at higher energies than those for the corresponding tricarbonyl complexes [40]. Moreover, the mean $\nu(\text{CO})$ value in the case of the selenocarbonyl derivative is higher than that for the thiocarbonyl derivative. The $\nu(\text{CX})$ ($\text{X} = \text{S, Se}$) modes for the A and B isomers appear as one unresolved peak. As will be shown below, the ^{31}P NMR data for the complexes proved crucial in verifying the presence of the two isomers and in establishing their rela-

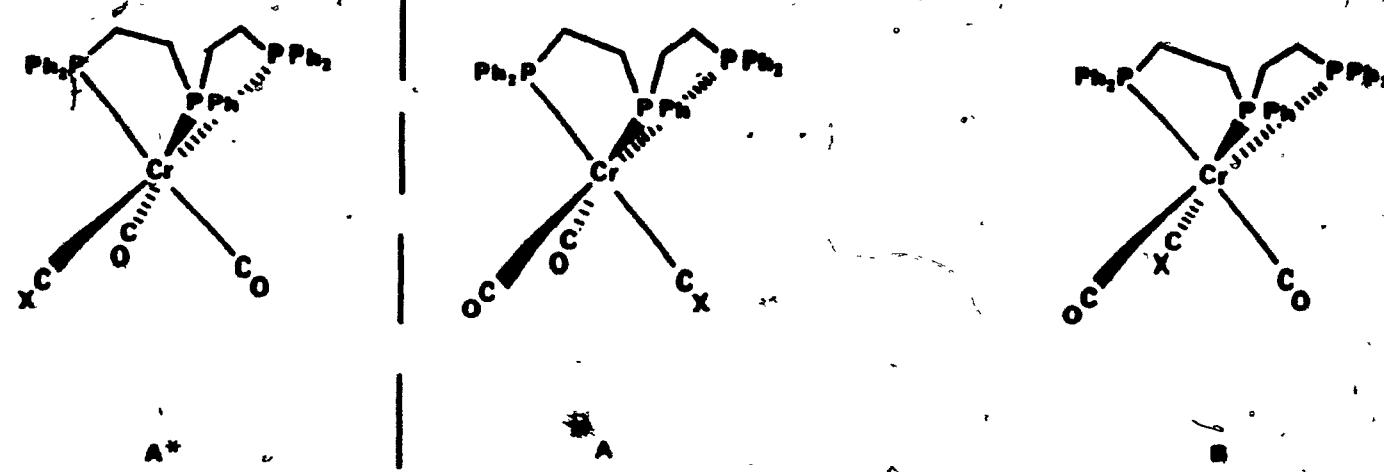

Figure 2.13. The two possible isomers of (triphos)Cr(CO)₂(CX) (X = S, Se). Isomer A exists in two enantiomeric forms.

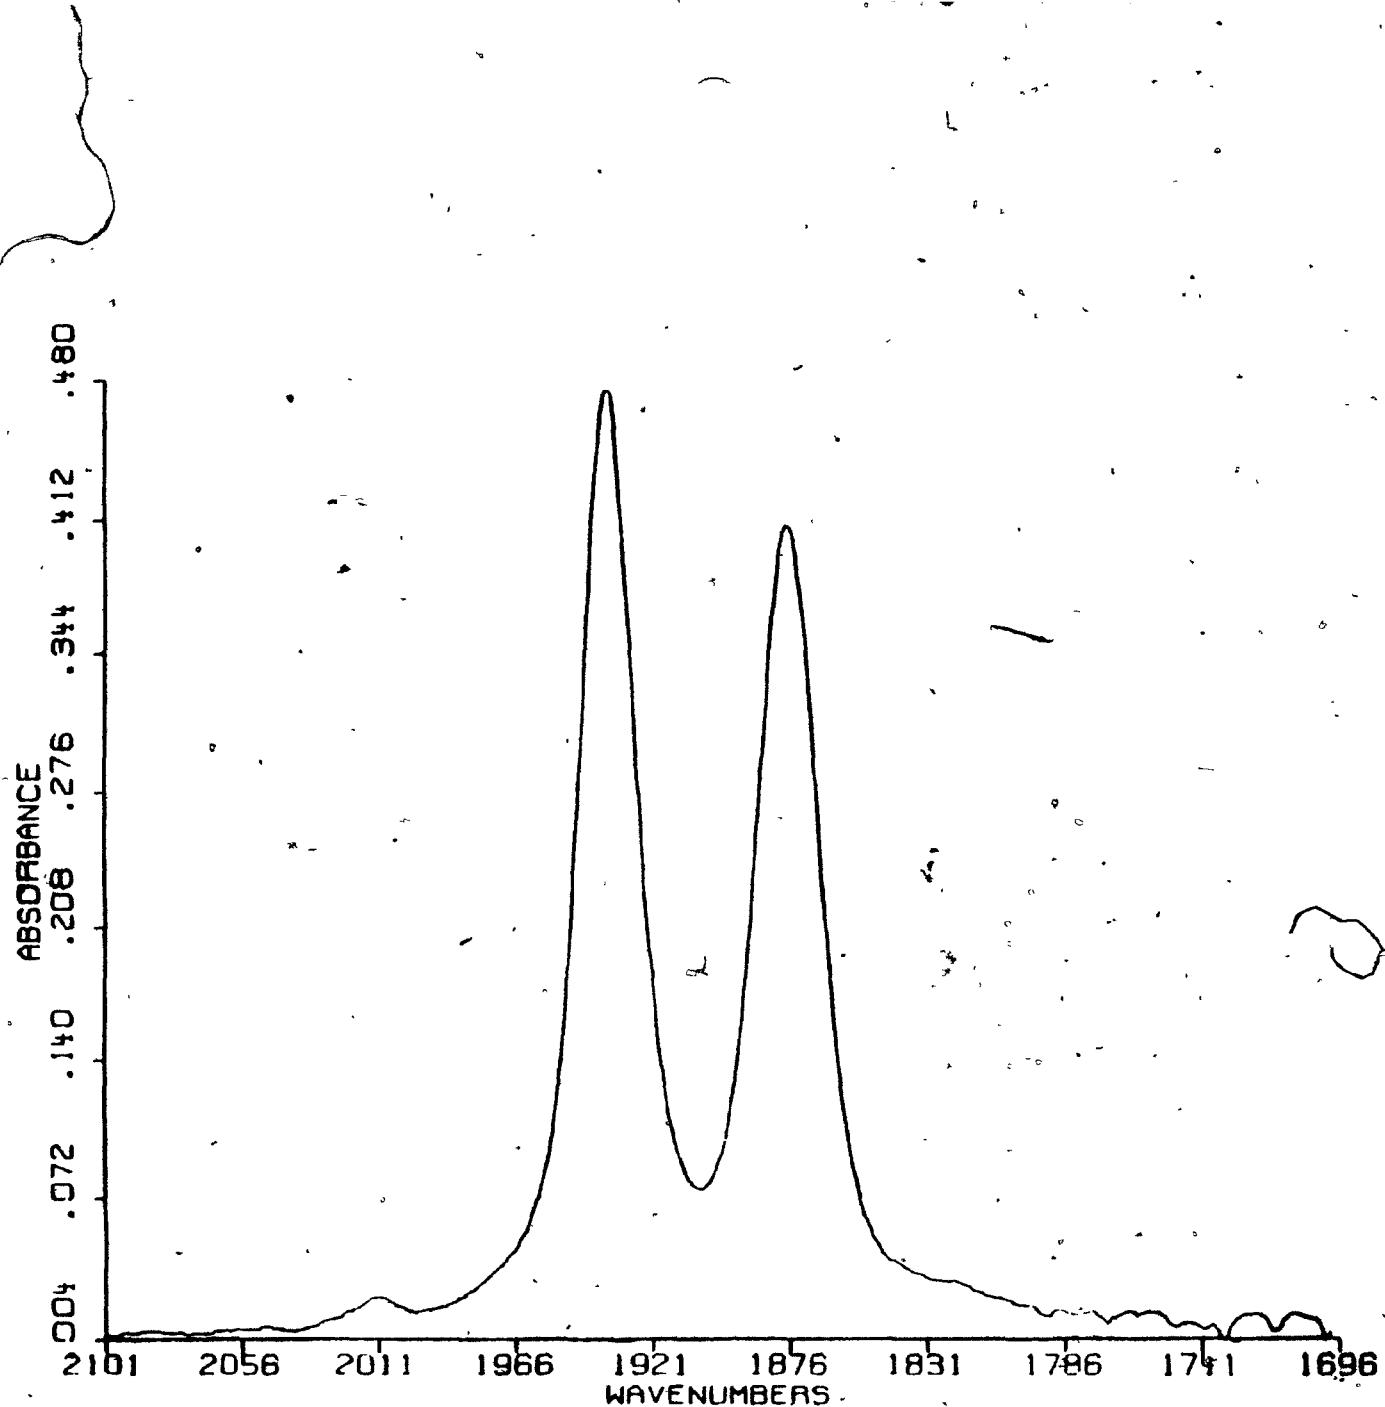

Figure 2.14. The $\nu(\text{CO})$ region of the FT-IR spectrum of (triphos) $\text{Cr}(\text{CO})_2(\text{CSe})$ in CH_2Cl_2 .

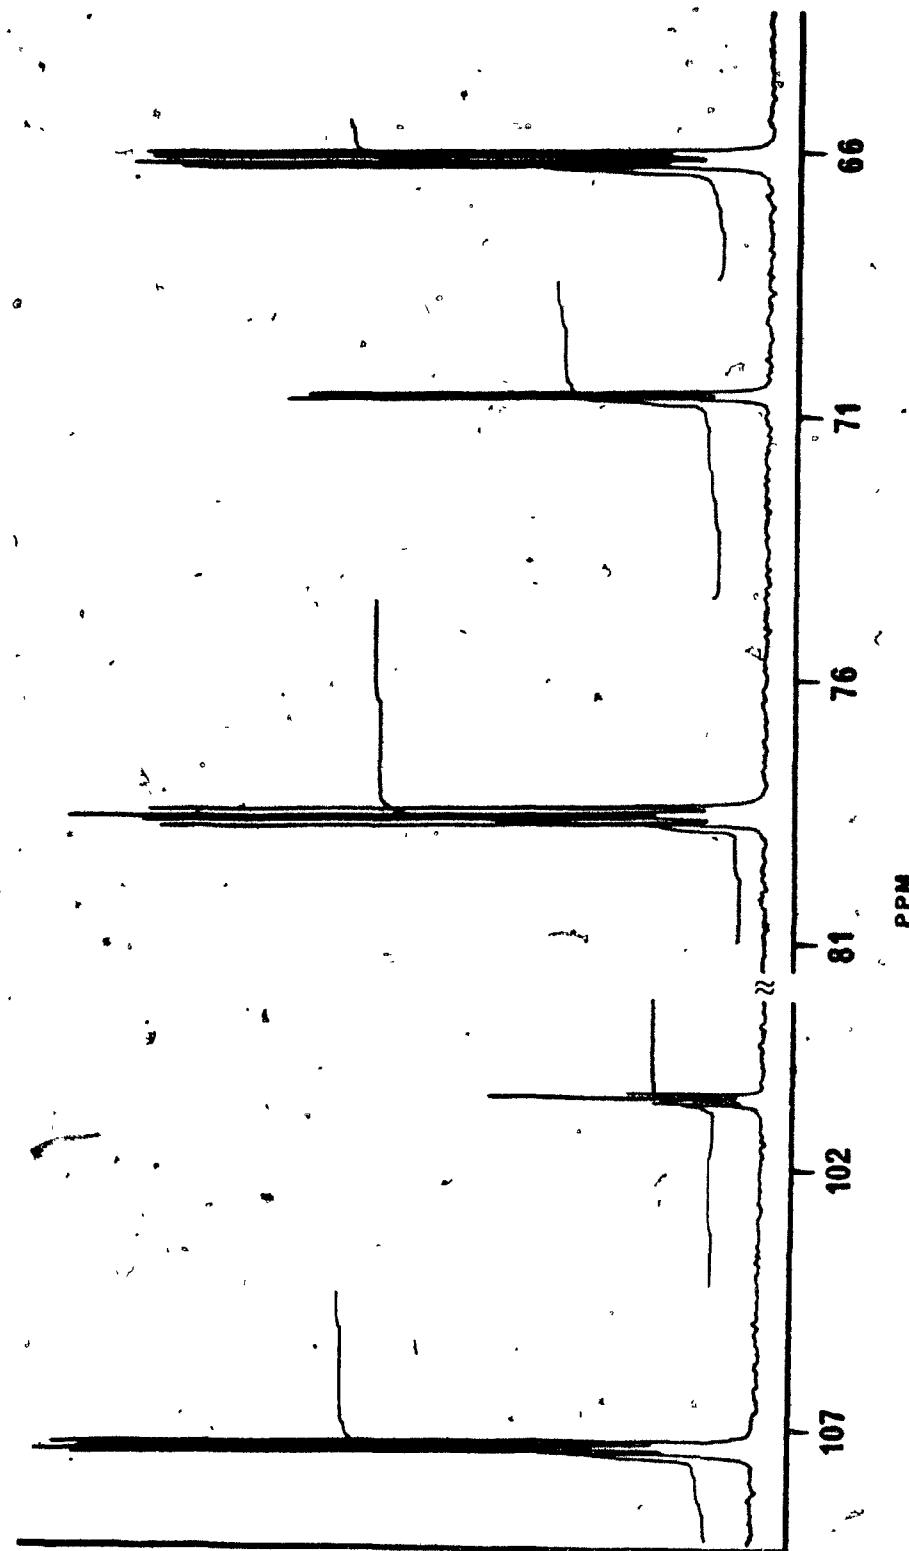

tive concentrations.

Isomer A (and A*) of (triphos)Cr(CO)₂(CX) (X = S, Se) is expected to exhibit three ³¹P NMR signals since the two terminal phosphorus atoms of the triphos ligand are trans to different ligands and the bridging phosphorus atom is in a different environment from the other two phosphorus atoms in the pure ligand. Isomer B with the bridging phosphine trans to the CX ligand is expected to have two signals since the terminal phosphorus nuclei experience identical environments. The isomers were detected in the ³¹P NMR spectrum (Figure 2.15) in a 4:1 ratio (A: B). The assignment of the resonances for isomer A was facilitated by comparison with the spectrum of the parent tricarbonyl which enabled the resonance due to the bridging phosphorus atom to be easily identified. The resonances due to the terminal phosphorus atoms were assigned on the basis of the trend observed for ³¹P resonances in the chalcocarbonyl complexes presented in this chapter. Thus, the resonance at higher field was assigned to the phosphorus atom trans to CX (X = S, Se). The ³¹P NMR spectrum of isomer B was directly assigned by comparison with the spectrum of (triphos)Cr(CO)₃ [41].

2.3.5. Attempted Synthesis of (cht)Cr(CO)₂(CS)

In Chapter 4 of this thesis, a kinetic investigation of

Figure 2.15. ^{31}P NMR spectrum of (triphos)Cr(CO)₂(CSe) in C₆D₅CD₃. Conditions: obtained on a Varian XL-300 FT spectrometer operating at 121.42 MHz; ^1H -decoupled; sweep width = 6,300 Hz; offset = 10,200 Hz; flip angle = 66°; repetition time = 20 s; number of scans = 200.

INTENSITY

arene displacement reactions of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S, Se}$) complexes with $(\text{RO})_3\text{P}$ ligands will be presented. Similar kinetic studies have been reported in the literature for $(\text{cht})\text{M}(\text{CO})_3$ ($\text{M} = \text{Cr, Mo, W}$) and $(\eta\text{-Arene})\text{M}(\text{CO})_3$ ($\text{M} = \text{Mo, W}$) but not for $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ complexes because the reactions are too slow. It would be of interest to compare kinetic data for tricarbonyl, thiocarbonyl and selenocarbonyl complexes. However, it appears that molybdenum and tungsten arene thiocarbonyls are not accessible [5] due to the inability to photochemically or thermally generate the $(\eta\text{-Arene})\text{M}(\text{CO})_2(\text{L})$ ($\text{L} = \text{C}_8\text{H}_{14}, \text{THF}$) precursor necessary to afford $(\eta\text{-Arene})\text{M}(\text{CO})_2(\text{CS})$ [1]. Therefore, synthesis of $(\text{cht})\text{Cr}(\text{CO})_2(\text{CS})$ was attempted in an effort to obtain a basis for direct comparison of the effects of CS and CO ligands on the lability of the metal-arene bond in analogous complexes. The conventional synthetic route to thiocarbonyls through photolysis of the parent tricarbonyl complex in cis-cyclooctene and subsequent addition of CS_2 to yield the thiocarbonyl complex [1] proved unfeasible because $(\text{cht})\text{Cr}(\text{CO})_3$ was photochemically inactive under the conditions employed. Only one research group has obtained spectroscopic evidence for photochemical formation of $(\text{cht})\text{Cr}(\text{CO})_2(\text{L})$ [$\text{L} = \text{py, } (\text{PhO})_3\text{P}$], this after irradiation for 40 h at -40°C [42]. For $\text{L} = \text{C}_8\text{H}_{14}$, no product formation was detected. Consequently, they postulated initial forma-

tion of (η^4 -cht)Cr(CO)₃(L) prior to CO dissociation for the reactions where L = py and (PhO)₃P. The poor nucleophilicity and the size of the cyclooctene ligand may hinder its binding to the metal at such a low temperature [42]. In the present work UV photolysis of (cht)Cr(CO)₃ in 1:1 toluene/cyclooctene at 0°C and at room temperature produced no detectable concentration of the cyclooctene complex. Heating the sample in conjunction with photolysis resulted in decomposition. The ring exchange procedure, which was reported for the synthesis of (cht)M(CO)₃ (M = Mo, W) from (η -Arene)M(CO)₃ in excess cht [25], resulted in decomposition in the case of (mbz)Cr(CO)₂(CS). Another synthetic route to (cht)Cr(CO)₃ involves refluxing a mixture of cht and Cr(CO)₆ either in neat ligand or in a high-boiling solvent such as heptane [25]. Therefore, Cr(CO)₅(CS) was synthesized following the established procedure [20], and its reaction with cht was investigated. After refluxing for 24 h, no product was obtained. Finally, attempted synthesis of Cr(CO)₂(CS)(CH₃CN)₃ from either (η -Arene)Cr(CO)₂(CS) or Cr(CO)₅(CS) resulted in decomposition. This complex would have provided another route to the coordination of cht to the chromium thiocarbonyl moiety, as demonstrated by the synthesis of (cht)W(CO)₃ from W(CO)₃(RCN)₃ (R = alkyl) [43].

Chapter 3

Intramolecular Isomerization of Cr(CO)₂(CX)[(MeO)₃P]₃ (X = O, S, Se) Complexes

3.1 Introduction

An unexpected feature of the arene displacement reactions of (η -Arene)Cr(CO)₂(CX) (X = S, Se) complexes investigated in Chapter 2 is the involvement of an isomerization process. The major product isolated from these reactions has been characterized as the mer I isomer and not the fac isomer observed as the major product in triene displacement reactions of Group VIB (cht)M(CO)₃ and arene displacement reactions of (η -Arene)M(CO)₃ (M = Mo, W). The formation of the mer I isomer may be postulated to result from the isomerization of an intermediate in the reaction pathway. However, in recent years several reports have appeared in the literature [1-10] of intramolecular isomerization of Group VIB metal carbonyl complexes. Accordingly, the possibility that mer-Cr(CO)₂(CX)[(MeO)₃P]₃ complexes are formed as a result of the intramolecular isomerization of the corresponding fac isomers was investigated.

Intramolecular rearrangement of octahedral complexes is thought to proceed through either a trigonal prismatic [11] or bicapped-tetrahedral [12] intermediate or transition

state. The schematic representation of these processes is shown in Figure 3.1. One of the first examples reported of intramolecular rearrangement in Group VIB metal carbonyl complexes was the isomerization of $\text{Cr}(\text{CO})_4[\text{C}(\text{OMe})\text{Me}](\text{R}_3\text{P})$ ($\text{R} = \text{Et, Cy}$) [1,2]. Shortly after, the thiocarbonyl-containing complex $\text{trans-W}(\text{CO})_4(^{13}\text{CO})(\text{CS})$ was investigated by Angelici and his co-workers and was also shown to undergo isomerization through a non-dissociative mechanism [3]. Since then, Dahrensborg and his research group have found that other complexes such as $\text{M}(\text{CO})_{6-n}(\text{R}_3\text{P})_n$ ($\text{M} = \text{Cr, Mo, W}; n = 1, 2; \text{R} = \text{Me, Et, } i\text{-Pr, } n\text{-Bu, OMe, OEt}$) undergo isomerization by a non-dissociative pathway [4-7], with the rate of rearrangement decreasing in the order $\text{Cr} > \text{W} > \text{Mo}$ [6,7]. Similarly intramolecular isomerization of $\text{M}(\text{CO})_4(\text{PF}_3)_2$ ($\text{M} = \text{Cr, Mo, W}$) has been reported [8]. Activation parameters were determined for some of the above complexes (Table 3.1). In the case of the chromium and tungsten complexes $\text{trans-Cr}(\text{CO})_4(^{13}\text{CO})(\text{Et}_3\text{P})$ [7] and $\text{trans-W}(\text{CO})_4(^{13}\text{CO})(\text{CS})$ [3], large positive enthalpies of activation and positive entropies of activation were obtained for the isomerization to the cis isomers. On the basis of the large enthalpies of activation, significant bond lengthening in the activated states was postulated to occur. For $\text{trans-W}(\text{CO})_4(^{13}\text{CO})(\text{Et}_3\text{P})$ [7], isomerization exhibited a small enthalpy and a large negative entropy, supportive of a trigonal prismatic twist.

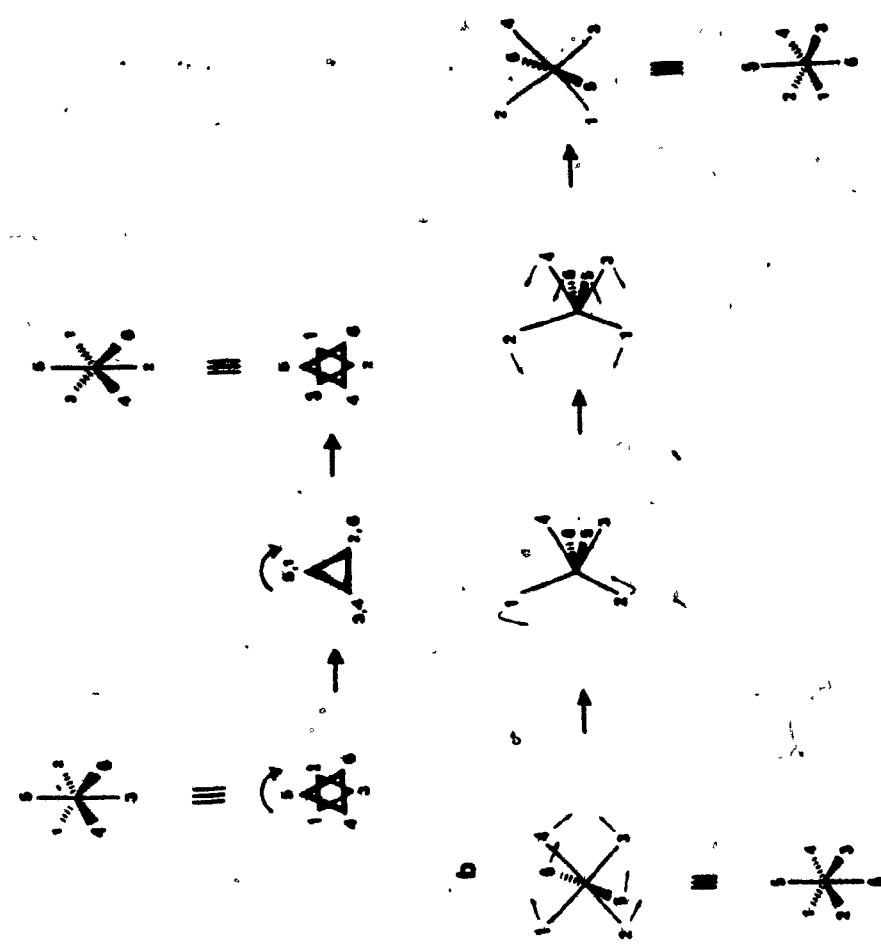

Figure 3.1. Proposed rearrangement pathways available to octahedral complexes: (a) through a trigonal prismatic intermediate; (b) through a bicapped-tetrahedral intermediate.

3.2 Experimental

3.2.1 Synthesis of Cr(CO)₂(¹³CO)₃(CS)

(mbz)Cr(CO)₂(CS) (10 mg) was dissolved in 10 ml of THF and transferred under N₂ to a specially constructed high-pressure stainless steel reaction vessel, lined with a Teflon jacket and connected to a second stainless steel chamber containing a measured amount of ¹³CO (transferred on a vacuum line through a manometer and adsorbed on charcoal at 77 K). The solution was degassed by three freeze-thaw cycles and frozen in liquid nitrogen. The ¹³CO was transferred to the solution chamber to give 20 atm pressure. The valve to the ¹³CO storage chamber was then closed. The solution was heated at 65°C for periods of 6-24 h. Unreacted ¹³CO was then readSORBED on the charcoal in the storage chamber by opening the valve between the chambers while both were submerged in liquid N₂. The product was isolated by evaporation of the solvent under reduced pressure with the temperature maintained at -15°C due to the volatility of Cr(CO)₅(CS) [13]. ¹³C NMR (10 scans) (relative to TMS): 212.1 (d, J = 5 Hz, cis CO) and 209.2 ppm (t, J = 5 Hz, trans CO). FT-IR (CS₂): ν(CO) 2066(m), 2056(w), 2008(m), 1988(m), 1978(s), 1958(vs), 1956(vs), 1945(m) cm⁻¹. The high-resolution mass spectrum of the product was obtained with a DuPont 21-492B spectrometer interfaced to a Hewlett Packard computer. Mol. wt: calculated for ¹³C₃¹²C₃O₅SCR, 238.897; found, 238.894.

When the above reaction was carried out with less than 1 atm ^{13}CO pressure, partial decomposition of the starting material was observed. With the use of octane in place of THF as solvent under identical conditions to those described in the above procedure, no reaction occurred and the starting material was recovered with no observed decomposition.

3.2.2 Kinetic Investigation of Isomerization of $\text{Cr}(\text{CO})_2-$

The fac \longrightarrow mer I isomerization reactions of $\text{Cr}(\text{CO})_2(\text{CX})-(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{O}, \text{S}, \text{Se}$) were monitored by FT-IR spectroscopy. Solutions of complex in DCE were prepared and transferred under nitrogen to a thermostatted IR cell (0.1 mm pathlength, NaCl windows) (constructed in-house in accordance with a design published in Reference 14). The thermostatted cell assembly was placed in the IR beam, and IR spectra were acquired at recorded time intervals. The rate of fac + mer isomerization for the tricarbonyl complex was followed by monitoring the decrease of the $a_1 \nu(\text{CO})$ peak of the fac isomer, while the rate of mer I \rightarrow fac isomerization for the thio- and selenocarbonyl derivatives was monitored by the growth of the $a' \nu(\text{CO})$ peak of the fac isomer. Rate constants ($k_1 + k_{-1}$) were calculated from the first-order rate plot of $\ln[A_e/(A_e - A_t)]$ vs. time, where A_t is the absorbance at time t and A_e is the absorbance at equili-

brium, using a linear least-squares program (Plotrax 2 from Engineering-Science Inc., Atlanta, Georgia, U.S.A.). The rate constants for the forward and reverse reactions were obtained by solving the equations:

$$k_c = k_1 + k_{-1}$$

$$K_{eq} = k_1/k_{-1}$$

where k_c is the calculated rate constant and K_{eq} was determined from the integrated areas of the resonances of the isomers in the ^{31}P NMR spectrum recorded on a Varian XL-300 NMR spectrometer. The activation parameters were calculated from the rate constants at three different temperatures.

3.2.3 Monitoring of Stereochemically Nonrigid Behaviour of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($X = \text{O}, \text{S}, \text{Se}$) Complexes

Two-dimensional (2-D) NOE ^{31}P NMR experiments were performed on a Varian XL-300 spectrometer, equipped with a 5-mm broad-band probe. $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($X = \text{O}, \text{S}, \text{Se}$) was dissolved under N_2 in deuterotoluene and heated in the probe at temperatures ranging from 30–80°C. Usually 4–32 transients were co-added to achieve a good signal-to-noise ratio. A total of 128 or 256 FIDs were acquired and zero filling was performed in the evolution domain. The 2-D NOE Accordan pulse sequence used was: $(\pi/2, t_1, \pi/2, \text{mix}, \pi, t_2)$ with a repetition delay of 2 s and incrementing the

mixing time according to the equation $t_{\text{mix}} = \kappa \times t_1$ with $\kappa = 30$. ^{31}P nuclei were proton-decoupled during the evolution and detection periods. The FIDs were collected in either a [512 x 512] or [1024 x 1024] matrix. The data matrix was Fourier transformed in two dimensions and plotted by a contour plot program. The digital resolution in the evolution domain is sw_2/NI , where sw_2 is the spectral width in the evolution domain and NI is the number of increments or FIDs, while the digital resolution in the detection domain is equal to 1/AT (AT = acquisition time) and is approximately 8 Hz.

3.3 Results and Discussion

The isomerization of mer-Cr(CO)₂(CX)[(MeO)₃P]₃ (X = S, Se) in solution at room temperature was established by monitoring the changes with time in the carbonyl region of the IR spectrum of the pure mer I isomer, obtained by TLC purification as described in Chapter 2. The mer I to fac interconversion is illustrated in Figure 3.2 for the case of the selenocarbonyl derivative, displaying the growth of the peak at 1962 cm^{-1} characteristic of the fac isomer (Figure 2.8).

The study was also extended to the analogous fac-Cr(CO)₃[(MeO)₃P]₃ complex. The higher-frequency $\nu(\text{CO})$ mode in the FT-IR spectrum of this complex in solution at room

temperature was observed to decrease with time, accompanied by the growth of a new peak at 1977 cm^{-1} (Figure 3.3) attributable to mer- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ (see Table 2.7). The intensity of the second $\nu(\text{CO})$ mode of the fac isomer increased with time due to its coincidence with the intense lower-frequency $\nu(\text{CO})$ mode of the mer isomer (Figure 3.4). Thus fac- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ has been shown to also undergo rearrangement in solution at room temperature. In a recent publication [9], electrochemical oxidation has been reported to induce intramolecular isomerization of fac- $\text{M}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ ($\text{M} = \text{Cr}, \text{Mo}$). This process occurs through the generation of the fac- $\{\text{M}(\text{CO})_3[(\text{MeO})_3\text{P}]_3\}^+$ cationic complex which undergoes rapid conversion to mer- $\{\text{M}(\text{CO})_3[(\text{MeO})_3\text{P}]_3\}^+$. Addition of one electron to the cationic mer isomer generates mer- $\text{M}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$. The authors mention that the neutral chromium complex also exhibits intramolecular isomerization, but at a much slower rate than the cation.

In order to establish that the isomerization of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$) proceeds through a non-dissociative mechanism, the isomerization of mer- $\text{Cr}(\text{CO})_2-(\text{CX})[(\text{MeO})_3\text{P}]_3$ was followed in solution in the presence of excess $(\text{PhO})_3\text{P}$ at 60°C using FT-IR spectroscopy. No incorporation of $(\text{PhO})_3\text{P}$ into the complex was observed, as evidenced by the lack of any peaks in the FT-IR difference spectrum of the equilibrium mixtures obtained in the

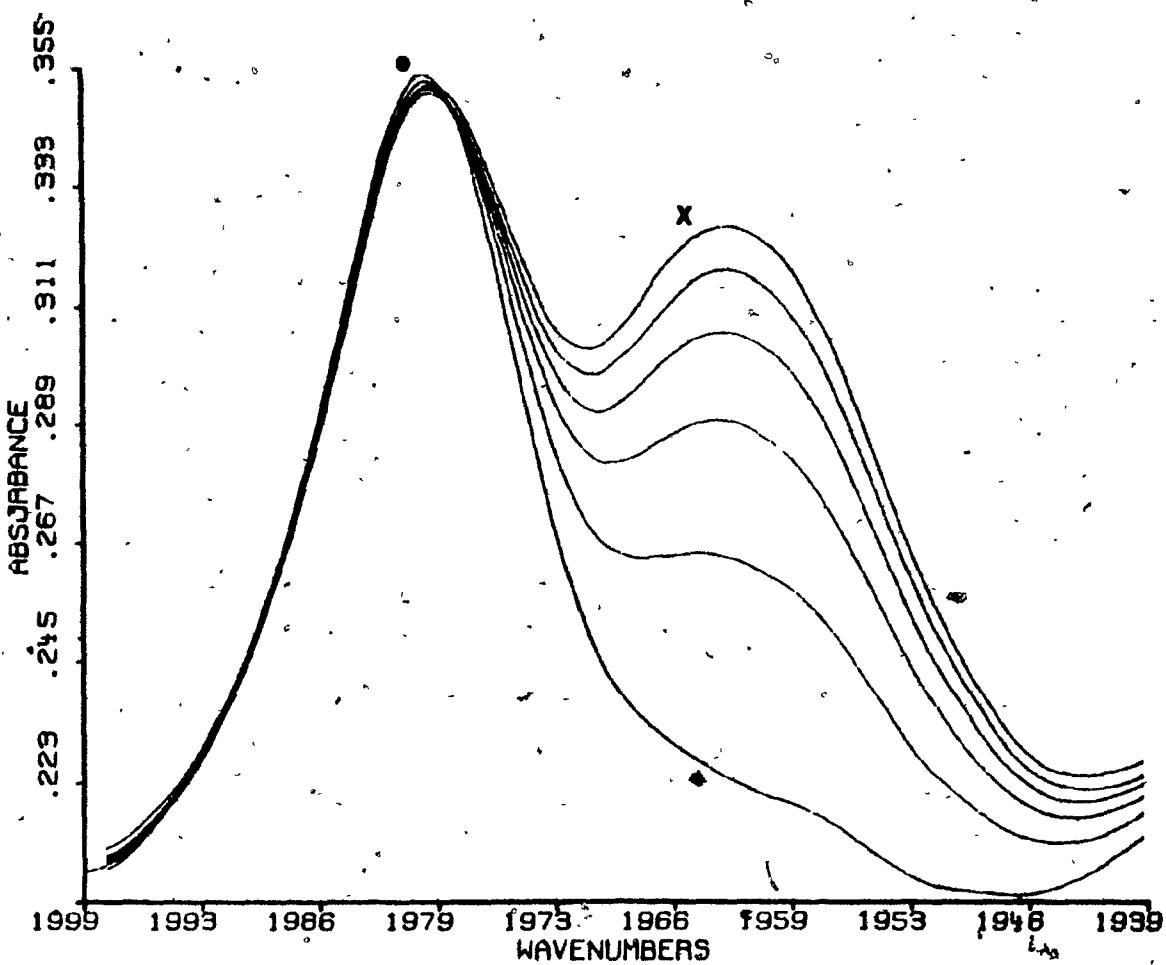

Figure 3.2. Isomerization of mer- $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$ (●) in dichloroethane solution at 38.0°C as monitored by FT-IR spectroscopy, showing the formation of fac- $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$ (X).

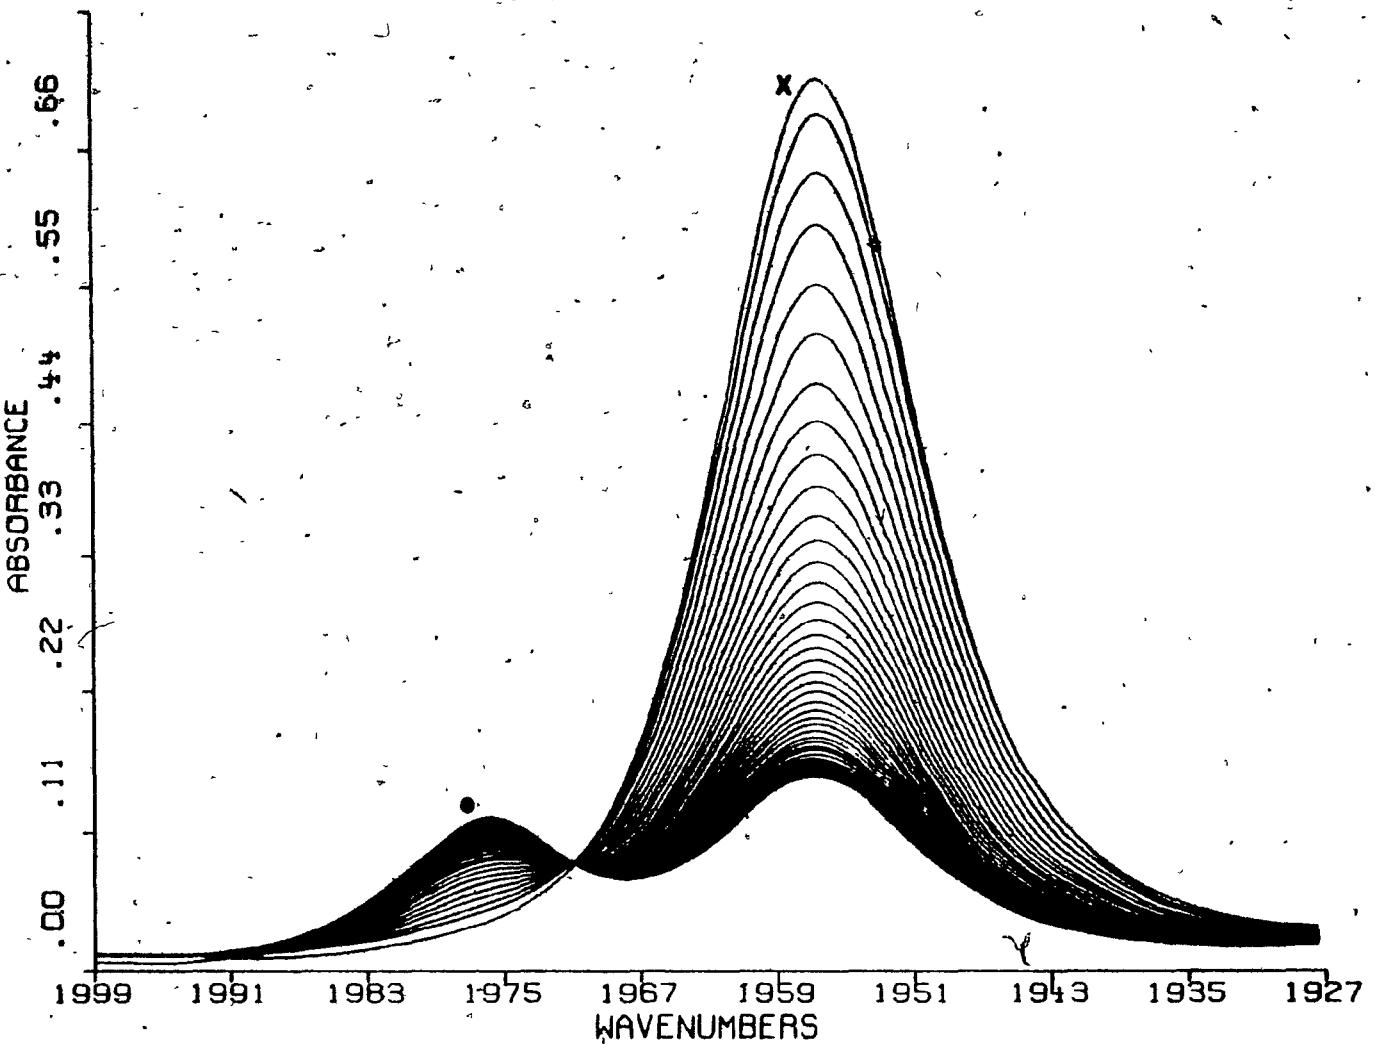

Figure 3.3. Isomerization of fac- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ (X) in dichloroethane solution at 49.2°C as monitored by FT-IR spectroscopy, showing the formation of mer- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ (●).

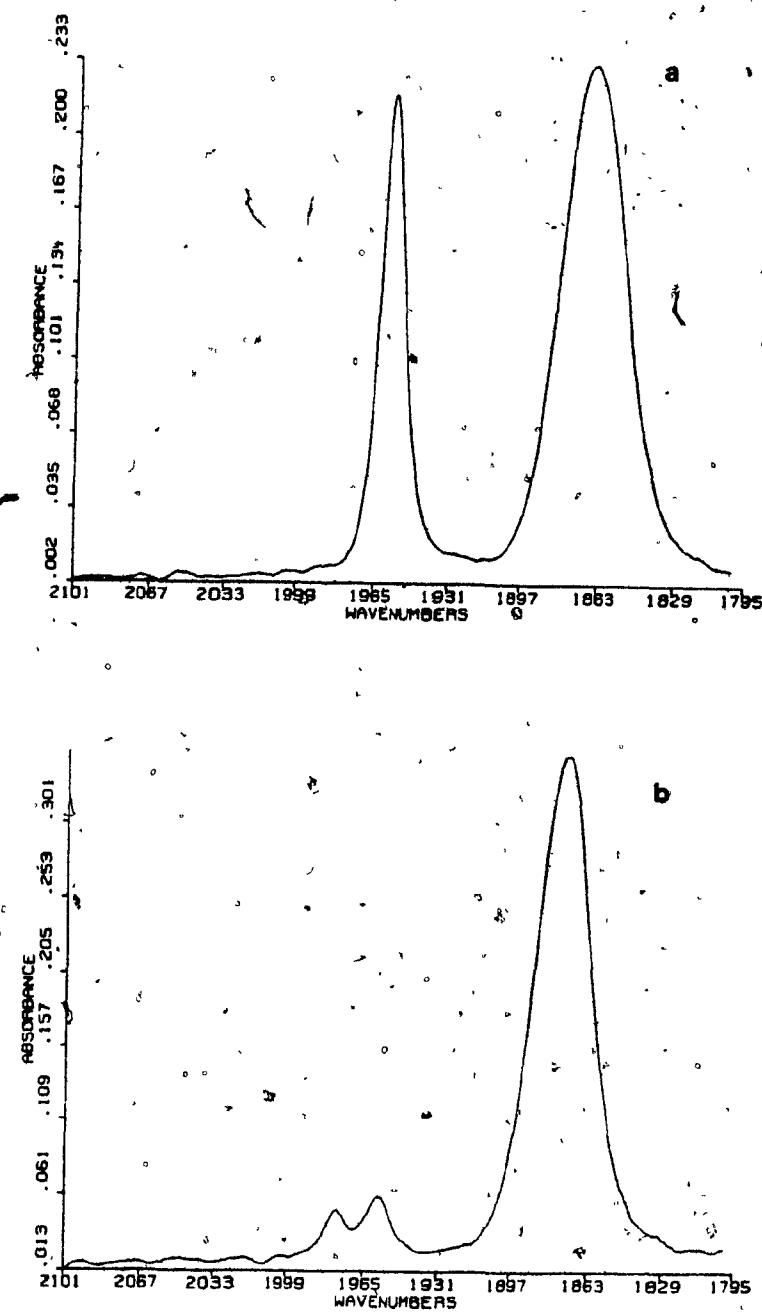

Figure 3.4. FT-IR spectra (in dichloroethane) in the carbonyl stretching region of (a) fac- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$, and (b) an equilibrium mixture of this complex and its mer isomer.

presence and absence of $(PhO)_3P$. Furthermore, there was no shift in the position of the isosbestic point obtained for the isomerization process. The above evidence indicates that the isomerization occurs through a non-dissociative pathway.

In a second experiment, arene displacement from $(mbz)Cr(CO)_2(CS)$ was effected in the presence of ^{13}CO at $60^\circ C$ for 6 h in THF to yield $Cr(CO)_2(^{13}CO)_3(CS)$. The splitting pattern in the ^{13}C NMR spectrum of this product (Figure 3.5) reveals that only three labelled carbonyl groups are present, while a fourth ^{13}CO ligand would have been incorporated if isomerization occurred by a dissociative mechanism subsequent to product formation. The two ^{13}CO resonances observed were identified on the basis of the previous assignment of the ^{13}C NMR spectrum of $Cr(CO)_5(GS)$ [13]. The higher-field resonance (209.2 ppm) is attributed to ^{13}CO trans to the CS ligand and is split into a triplet, while the lower-field resonance (212.1 ppm) due to ^{13}CO in the equatorial plane is split into a doublet. This splitting pattern is consistent with both the fac and mer I configurations of $Cr(CO)_2(CS)L_3$ ($L = ^{13}CO$), whereas the mer II isomer, having three ^{13}CO ligands in the equatorial plane, would give rise to a singlet which may be hidden under the doublet. While the number of isomers of $Cr(CO)_2(^{13}CO)(CS)$ in the sample thus cannot be established from the ^{13}C NMR

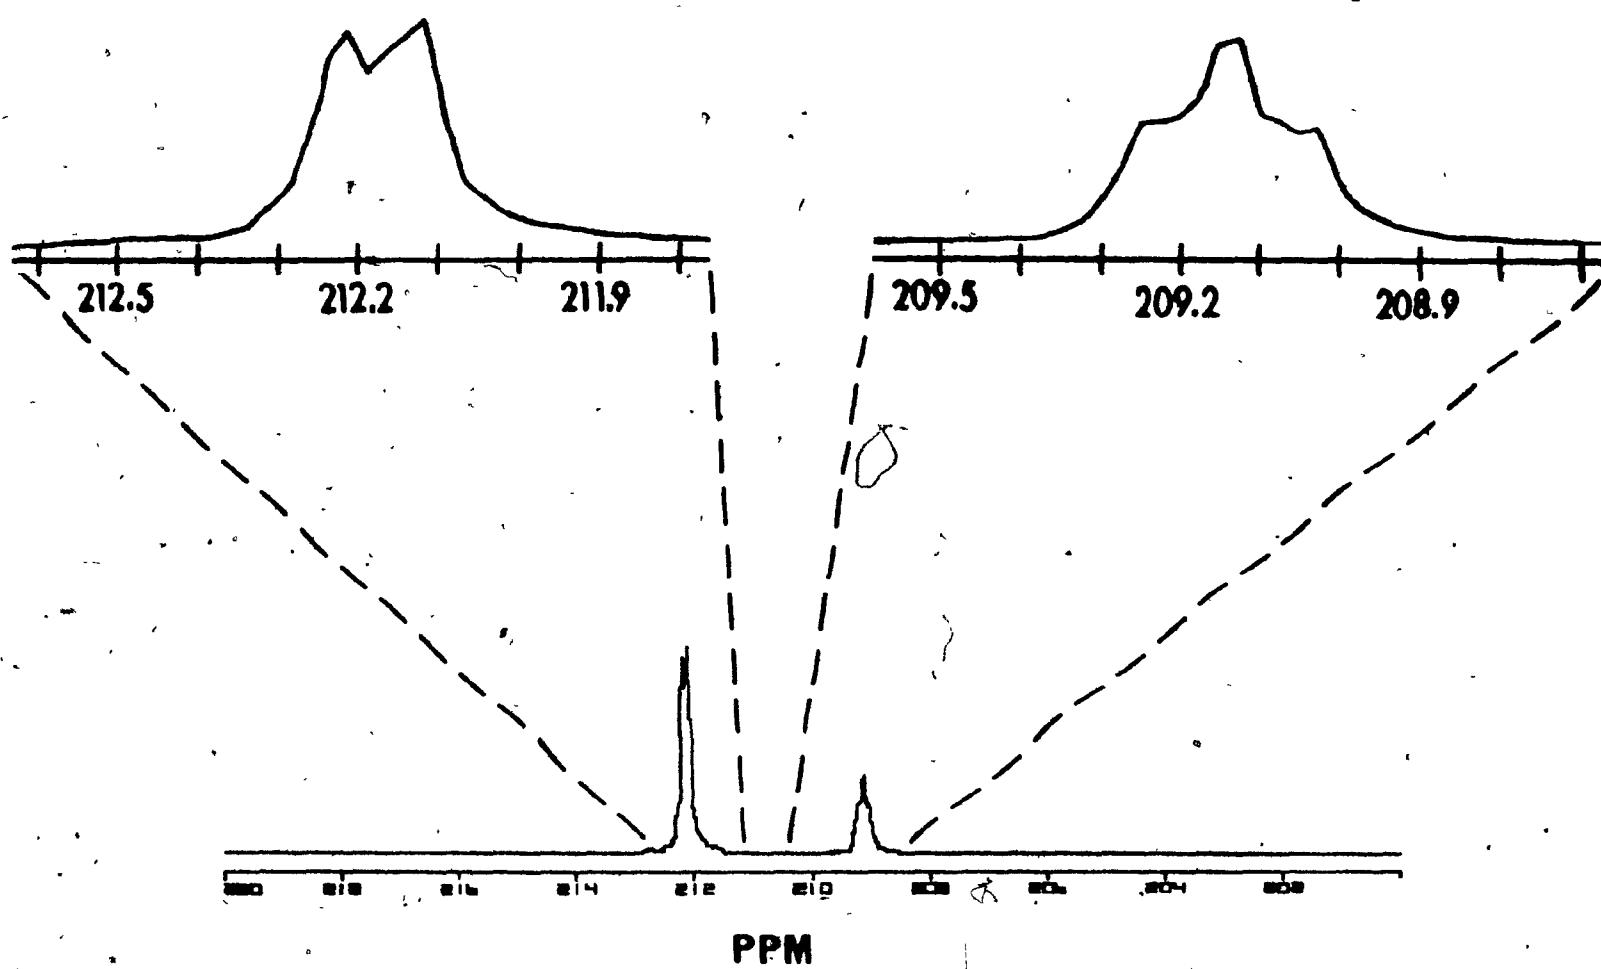

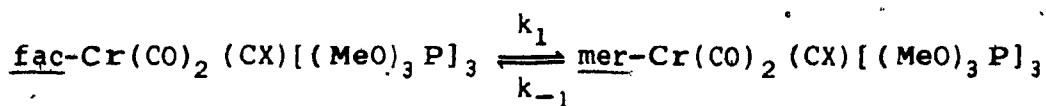

Figure 3.5. ^{13}C NMR spectrum of $\text{Cr}(\text{CO})_2(^{13}\text{CO})_3(\text{CS})$ in CD_2Cl_2 . Conditions: obtained on a Varian XL-200 FT spectrometer operating at 50.31 MHz; sweep width = 20,000 Hz; offset = 5,000 Hz; flip angle = 30° ; repetition time = 0.6 s; number of scans = 10. ⁶⁶

spectrum, the abundance of peaks in the carbonyl region of the IR spectrum (Figure 3.6) establishes that more than a single isomer is present. The observed frequencies are tabulated in Table 3.2, together with the frequencies calculated in the energy-factored force field approximation on the basis of force constants reported for $\text{Cr}(\text{CO})_5(\text{CS})$ [15]. The comparison of the observed and calculated frequencies reveals that $\underline{\text{fac}}\text{-}\text{Cr}(\text{CO})_2(^{13}\text{CO})_3(\text{CS})$ is present together with some amount of either the mer I or the mer II isomer or both. These results do not demonstrate definitively that $\text{Cr}(\text{CO})_2(^{13}\text{CO})_3(\text{CS})$ also undergoes intramolecular isomerization, since the observation of at least two isomers of this complex may be the result of a rearrangement process during the course of the arene displacement reaction. However, they do establish that if $\text{Cr}(\text{CO})_2(^{13}\text{CO})_3(\text{CS})$ does isomerize, it does so by a non-dissociative mechanism, as does $\text{W}(\text{CO})_4(^{13}\text{CO})(\text{CS})$ [3].

The rate constants for fac \rightarrow mer and mer \rightarrow fac isomerization of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$; mer = mer I) and $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ were calculated from the opposing first-order reactions

($\text{X} = \text{O}, \text{S}, \text{Se}$)

using the equations:

$$K_{eq} = k_1/k_{-1} = \frac{[\text{mer-Cr(CO)}_2(\text{CX})[(\text{MeO})_3\text{P}]_3]}{[\text{fac-Cr(CO)}_2(\text{CX})[(\text{MeO})_3\text{P}]_3]}$$

and

$$k_1 + k_{-1} = t^{-1} \ln A_e / (A_e - A_t)$$

where A_t is the absorbance at time t and A_e is the absorbance at equilibrium of a $\nu(\text{CO})$ mode in the FT-IR spectrum.

In order to determine the rates of the forward and reverse reactions, it was necessary to measure the distribution of the isomers at equilibrium. ^{31}P NMR spectroscopy was the technique chosen. The relative intensities of the peaks in a ^{31}P FT-NMR spectrum are a reliable measure of relative concentration providing the nuclei are given sufficient time to relax between pulses. Consequently, the spin-lattice relaxation times, T_1 , were determined for the isomers under investigation and the values obtained are shown in Table 3.3. It is of interest to note that the relaxation times decrease in the order $\text{P}_{\text{trans}} \rightarrow \text{P} > \text{P}_{\text{trans}} \rightarrow \text{CX}$ ($X = \text{O}, \text{S}, \text{Se}$). This trend has been observed for other $\text{M}(\text{CO})_n[\text{R}_3\text{P}]_{6-n}$ complexes and is attributed mainly to dipole-dipole relaxation [16]. Using gated decoupling, with an interval between pulses approximately ten times longer than

T_1 , thus allowing the nuclei sufficient time to relax, the relative ratios of the isomers present were obtained (Figures 3.7-3.9). The equilibrium constants were not found to be temperature dependent in the range of 20°C to 80°C. For all three complexes, the mer isomer (mer I in the case of the CS and CSe complexes) is predominant and the equilibrium mer/fac ratio is approximately the same ($K_{eq} = 5.0$).

Although the mer II isomer has not been observed spectroscopically by FT-IR or ^{13}C NMR, the ^{31}P NMR spectra of both the thiocarbonyl and selenocarbonyl complexes provided some empirical evidence of a minor component (~ 5% of the mer I isomer) with a splitting pattern and chemical shift values consistent with the mer II configuration (Figures 3.8 and 3.9). The appearance of a doublet and a triplet with a coupling constant similar to that of the mer I isomer indicates a structure in which two $(\text{MeO})_3\text{P}$ ligands are trans to each other and cis to a third $(\text{MeO})_3\text{P}$. The location of the triplet resonance downfield from the triplet of both fac and mer I isomers is indicative of a phosphorus trans to a CO rather than a CX, while the upfield shift of the doublet resonance relative to that of mer- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ (see Table 2.10), indicating a lower electron density at the metal centre, confirms the presence of a CX ligand. The low concentration of the mer II isomer relative to the fac or mer I isomer can be interpreted in terms of a site

Conditions: obtained on a Varian XL-300 FT spectrometer operating at 121.42 MHz; ^1H -decoupled; sweep width = 3,400 Hz; offset = 20,900 Hz; flip angle = 90° ; repetition time = 40 s; number of scans = 400.

preference of the CX ligand. In studies of the trans \rightarrow cis isomerization of a series of $W(CO)_4(CS)(L)$ complexes [17], it was found that $K_{eq} = [\text{cis}]/[\text{trans}]$ decreased with an increase in the ratio of σ -donor/ π -acceptor strength of the ligand L. Therefore, the thiocarbonyl ligand appears to exhibit a preference for a site trans to a strong σ -donor/weak π -acceptor. Consequently, the fac and mer I isomers of $Cr(CO)_2(CS)[(MeO)_3P]_3$, in which the CS ligand is trans to $(MeO)_3P$, would be predicted to be favoured with respect to the mer II isomer, in which CS is trans to CO. While the site preference of the CSe ligand has not been investigated, it is expected to be the same as that of CS, due to the similarity in the bonding properties of these ligands.

The rate constants for the fac \rightarrow mer isomerization of $Cr(CO)_2(CX)[(MeO)_3P]_3$ (mer I for X = S, Se) revealed that $k_1 > k_{-1}$ (Table 3.4) and that k_1 decreases in the order X = Se > S > O. The $\ln k_1$ vs $1/T$ plots are shown in Figure 3.10. The activation parameters for the forward and reverse processes are given in Table 3.5. The activation enthalpies are large and positive while the entropies are negative. Moreover, for the three chalcocarbonyl complexes examined, the forward and reverse reactions differ mainly in the entropy value, indicating steric factors determine the equilibrium ratio. The greater stability of the mer or mer I isomers may thus be postulated to result from the

decreased steric interaction between phosphite ligands in these isomers relative to the fac isomers.

Large enthalpies of activation have been measured for the intramolecular isomerization of other Group VIB metal carbonyl complexes (Table 3.1) and have been accounted for in terms of bond lengthening in the activated complex prior to or during the course of rearrangement [7]. In comparing the activation parameters of the selenocarbonyl and thiocarbonyl complexes to those of their tricarbonyl analogue, it is of interest to note that the enthalpy of activation is smaller for the former complexes. This is in line with the observed trans labilizing effect of CS and CSe ligands in dissociative processes. The increasing negative entropy of activation in the order O < S < Se can be related to the relative sizes of these atoms (Se > S > O).

Two-dimensional NMR spectroscopy [18] has recently been employed in the study of chemical exchange processes of organometallic complexes [19,20]. In the present work, a 2-D NOE ^{31}P NMR investigation demonstrated dynamic intramolecular interconversion between the mer I and mer II isomers of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$) taking place on the time scale of the NMR experiment at temperatures above 50°C (Figures 3.11-3.13). The intramolecular nature of the process was demonstrated by the lack of correlation in 2-D NMR between resonances of the complexes and those of excess ligand present in solution. However, the fac to mer I or

Figure 3.11. 2-D ^{31}P contour map for $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$ in deuterotoluene at 61°C on a Varian XL-300 spectrometer; an NOE accordian pulse sequence was employed with $K = 30$. All three isomers exhibit an AB_2 coupling pattern (chemical shifts are relative to H_3PO_4 as external standard): $\nabla = \underline{\text{mer II}}$ $\text{P}_2, \text{P}_3(\text{d})$ 191.4 ppm, $\text{P}_1(\text{t})$ 184.0 ppm ($J = 64$ Hz); $\bullet = \underline{\text{mer I}}$ $\text{P}_2, \text{P}_3(\text{d})$ 188.6 ppm, $\text{P}_1(\text{t})$ 181.2 ppm ($J = 64$ Hz); $\times = \underline{\text{fac}}$ $\text{P}_2, \text{P}_3(\text{d})$ 181.1 ppm, $\text{P}_1(\text{t})$ 178.5 ppm ($J = 72$ Hz).

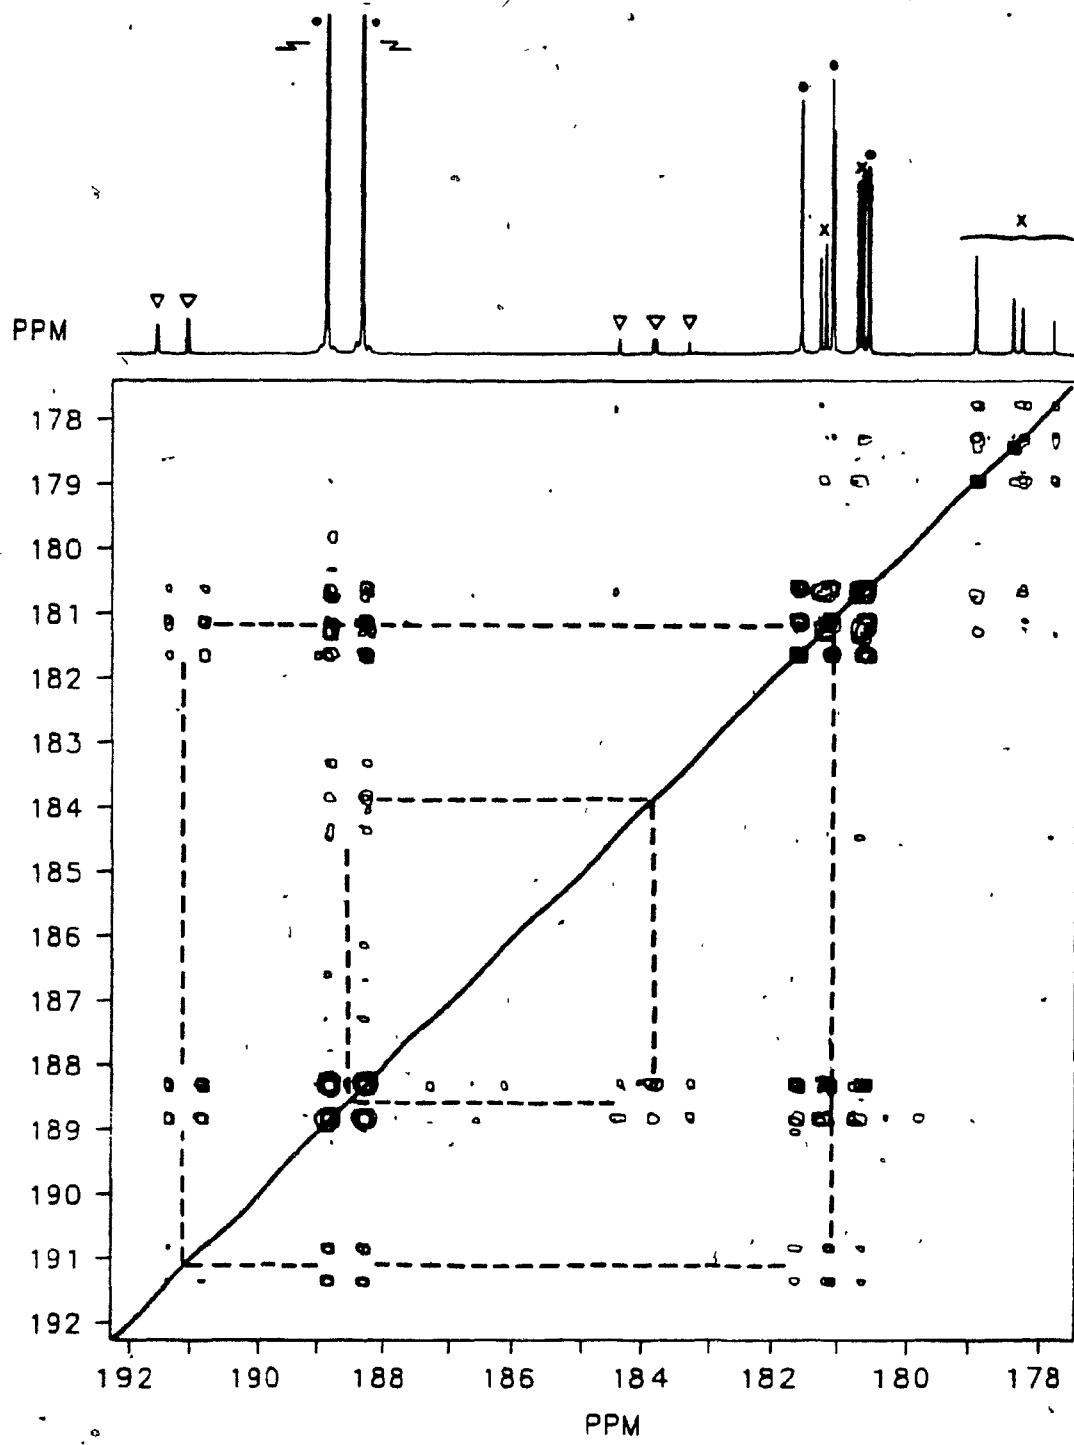

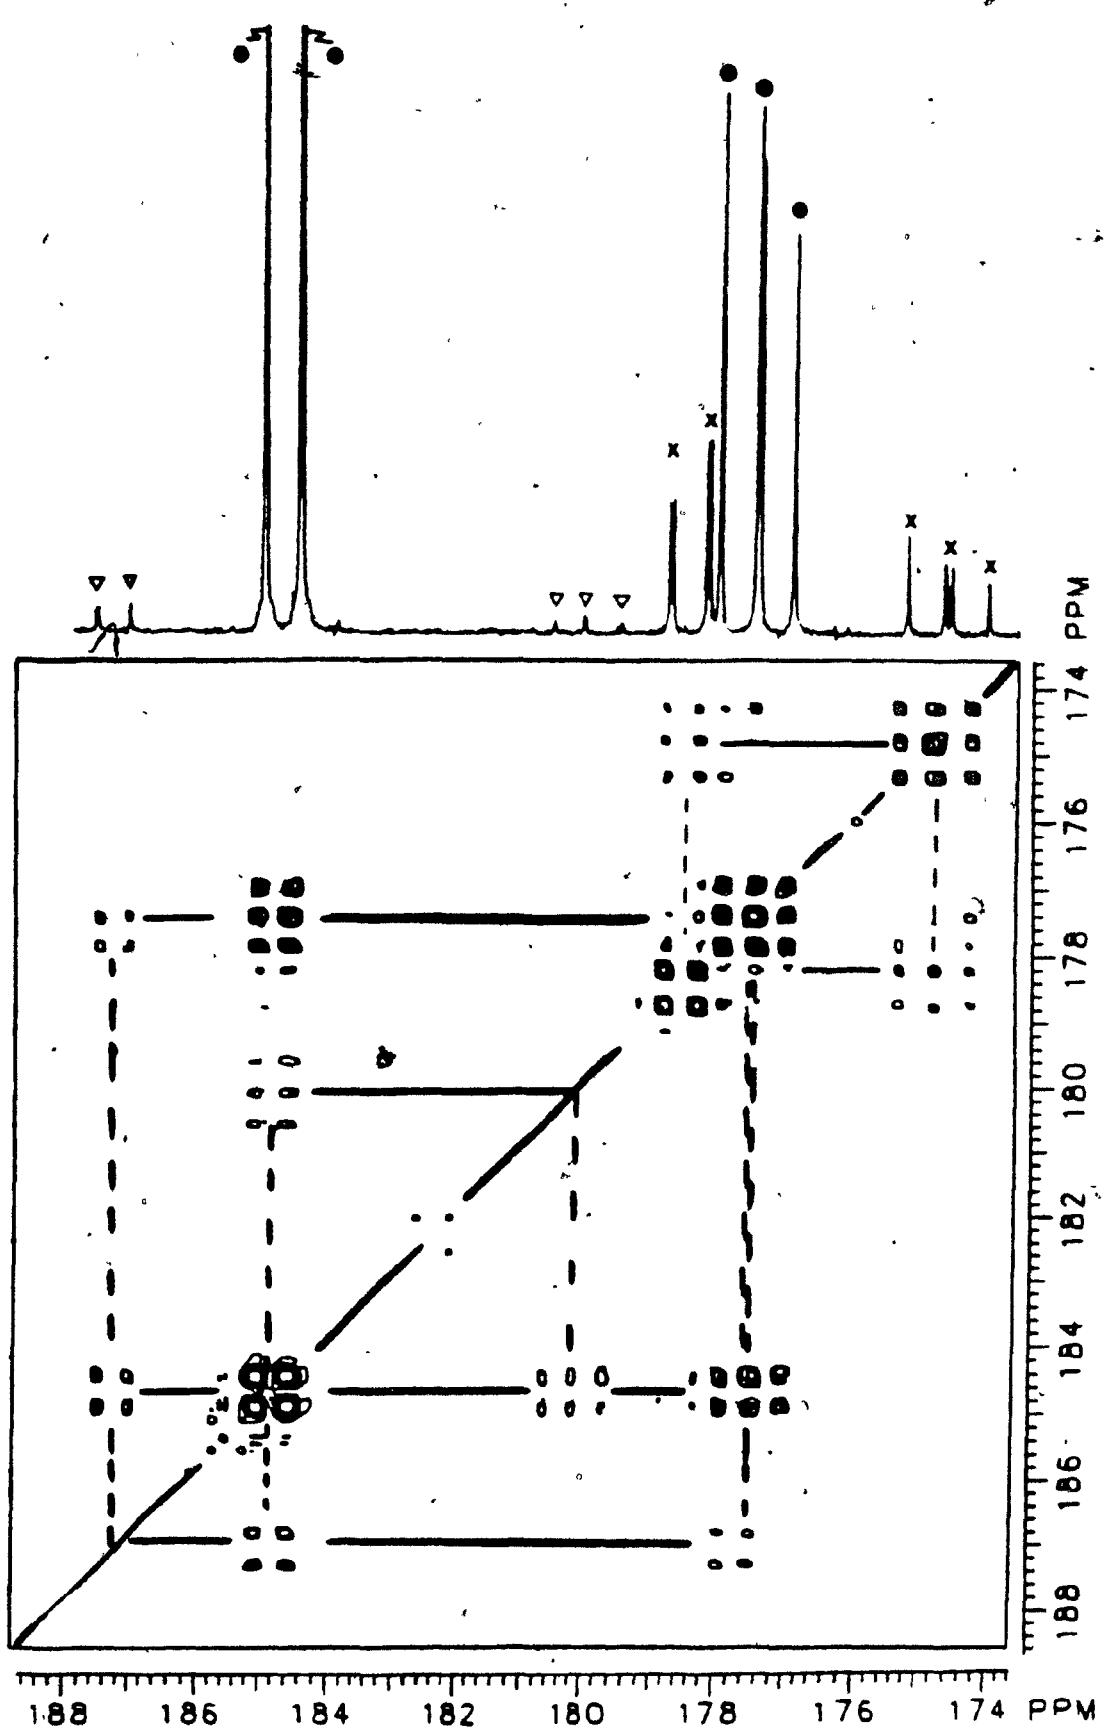

Figure 3.12. 2-D ^{31}P contour map for $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$ in deuterotoluene at 61°C on a Varian XL-300 spectrometer; an NOE accordian pulse sequence was employed with $\kappa = 30$. All three isomers exhibit an AB_2 coupling pattern (chemical shifts are relative to H_3PO_4 as external standard): $\nabla = \underline{\text{mer II}} \text{ P}_2, \text{P}_3(\text{d})$ 187.2 ppm, $\text{P}_1(\text{t})$ 180.3 ppm ($J = 63$ Hz); $\bullet = \underline{\text{mer I}} \text{ P}_2, \text{P}_3(\text{d})$ 184.9 ppm, $\text{P}_1(\text{t})$ 177.5 ppm ($J = 63$ Hz); $\times = \underline{\text{fac}} \text{ P}_2, \text{P}_3(\text{d})$ 178.6 ppm, $\text{P}_1(\text{t})$ 174.7 ppm ($J = 72$ Hz).

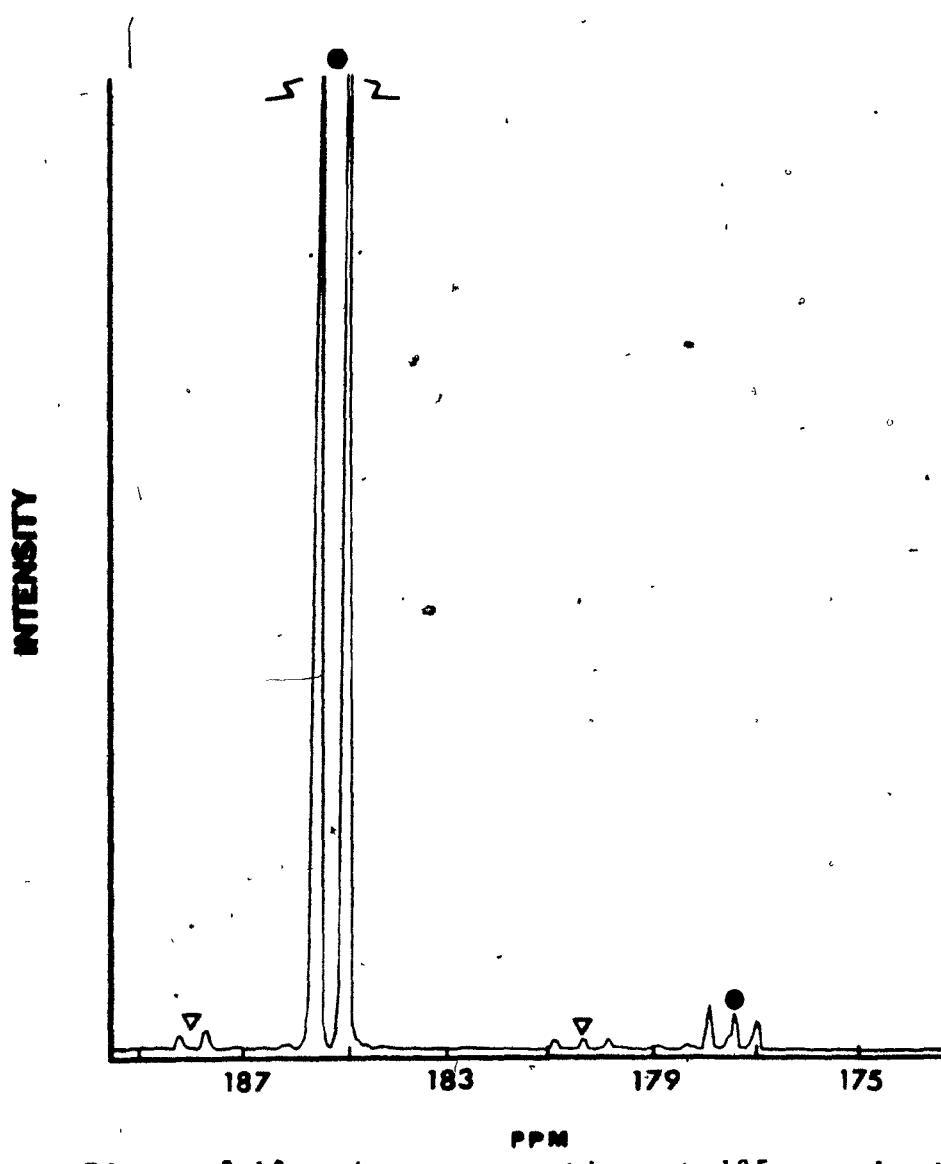

Figure 3.13. A cross section at 185 ppm in the evolution domain of Figure 3.12, displaying the correlation between the resonances of the mer I (●) and mer II (▽) isomers of $\text{Cr}(\text{CO})_2(\text{CSe})(\text{MeO})_3\text{P}]_3$.

fac to mer II interconversion was not observed at temperatures ranging up to 80°C for either the selenocarbonyl or the thiocarbonyl complex. Temperatures higher than 80°C resulted in some decomposition of these complexes.

The 2-D NMR studies of the mer I to mer II isomerization of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S, Se}$) provided information on the possible nature of the intermediates involved. The bicapped-tetrahedron mechanism would preserve the coupling pattern for each phosphorus nucleus in the two isomers (Figure 3.14). On the other hand, for the trigonal prismatic twist, the triplet of the mer I isomer would correlate with the doublet of the mer II isomer while the doublet of the mer I isomer would correlate with both the triplet and the doublet in the spectrum of the mer II isomer. The 2-D NMR spectra (Figures 3.11-3.12) illustrate both NOE and possible chemical exchange between the phosphorus nuclei of the same molecule by the distinct symmetrical off-diagonal contour on the exchange map. More importantly, however, the exchange of the mer I to mer II isomer provides convincing proof of dynamic rearrangement via a trigonal prism rather than a bicapped tetrahedron, as seen from the correlation of the off-diagonal peak of the doublet of the mer II isomer (bottom left-hand side of the contour map) to the doublet and triplet of mer I, while the triplet of the mer II is exchanging with the doublet of mer I.

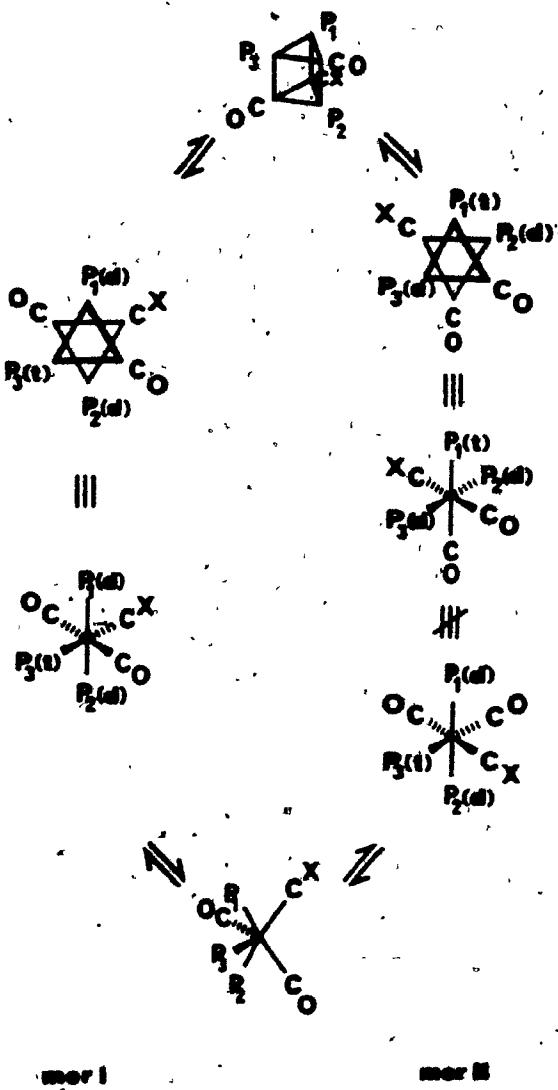

Figure 3.14. Schematic representation of possible pathways for the interconversion of the mer I and mer II isomers of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}$, Se): top, trigonal prismatic intermediate; bottom, bicapped-tetrahedral intermediate. For the sake of clarity, the $(\text{MeO})_3\text{P}$ ligands have been represented by P_1 , P_2 and P_3 .

On the basis of the observation that mer I + mer II isomerization of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S, Se}$) proceeds through a trigonal prismatic twist, it is highly probable that the mer I + fac isomerization of these complexes, as well as the fac + mer isomerization of the tricarbonyl analogue, occurs in the same manner. The failure to observe the dynamic interconversion of the fac and mer isomers may imply that the rearrangement is taking place at too slow a rate to be observed on the NMR time scale, i.e., that the phosphorus nuclei are relaxing at a faster rate than the time required for rearrangement to take place at these temperatures. This in turn indicates that the energy barrier for mer I to mer II isomerization is lower than that for mer → fac exchange. Figure 3.15 shows the schematic representation of the rearrangement of the thio- or selenocarbonyl complex through a trigonal prismatic twist. This mechanism should involve a large negative entropy for interconversion from mer I to fac due to the steric hindrance resulting from the eclipsing of two phosphites in the activated state. However, the interconversion of the mer I to mer II isomer should take place with a smaller entropy of activation; in this case, the activated state would have the phosphite ligands eclipsing CO and CX ligands, thus minimizing the steric effect. The activation parameters obtained for the interconversion of fac and mer isomers suggest that

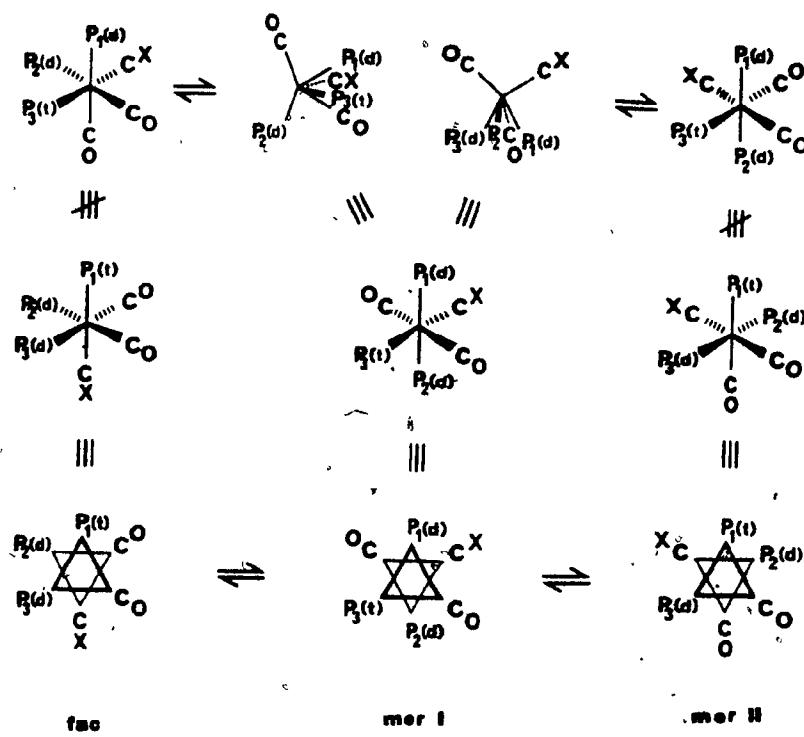

Figure 3.15. Schematic representation of the intramolecular isomerization of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ (X = S, Se) through trigonal prismatic (lower pathway) or bicapped-tetrahedral (upper pathway) intermediates.

in the assumed trigonal prismatic intermediate the unfavourable steric interactions between eclipsed pairs of ligands are minimized by the occurrence of some bond lengthening. Figure 3.15 illustrates that a 2-D NOE ^{31}P NMR experiment would allow the trigonal prismatic and bicapped-tetrahedron pathways to be distinguished in the case of fac + mer I isomerization as well, if this process could be detected. These two pathways would not be distinguished by 2-D ^{31}P NMR in the case of the tricarbonyl complex due to the simplicity of the spectrum of the fac isomer, with only a single resonance.

The observation of an off-diagonal correlation between the doublet and triplet of the fac isomer in the 2-D ^{31}P NMR spectrum of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$) (Figures 3.11 and 3.12) may be due to chemical exchange between equivalent fac isomers. The energy barrier for such a rearrangement by a trigonal prismatic mechanism would be expected to be of comparable size to the barrier for mer I to mer II interconversion since the activated state would involve in this case as well the eclipsing of each phosphite by a CO or CX ligand, rather than by a second phosphite ligand. However, the possibility that the observed correlation is solely due to NOE cannot be ruled out at the present time. It is, however, possible to distinguish chemical exchange between fac isomers and NOE in the case of (triphos) $\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S}, \text{Se}$), since two fac configurations of these complexes are

chemically distinguishable. Initial 2-D NOE ^{31}P NMR investigation of these complexes in deuterotoluene at temperatures ranging from 60–90°C revealed no off-diagonal correlation between the A and B isomers. However, the steric constraints and electronic properties of the triphos ligand are quite different from those of the trimethylphosphite ligands in fac- $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$, so that the evidence obtained for the triphos complexes is not necessarily pertinent to the trimethylphosphite complexes.

Vancea et al. have examined the stereochemical non-rigidity of cis- $\text{M}(\text{CO})_4(\text{ER}_3)_2$ ($\text{M} = \text{Fe}, \text{Ru}, \text{Os}; \text{E} = \text{Si}, \text{Ge}, \text{Sn}, \text{Pb}$; R = organic group or halogen) derivatives [21]. In these complexes, the axial and equatorial carbonyls exhibit one signal in the carbonyl region of the ^{13}C NMR spectrum at room temperature signifying that the axial and equatorial carbonyls are exchanging extremely fast on the NMR time scale, through an intramolecular rearrangement process. These complexes become stereochemically rigid at, or below, approximately -50°C. The crystal structures of cis- $\text{Fe}(\text{CO})_4(\text{SnPh}_3)_2$ [22] and cis- $\text{Fe}(\text{CO})_4(\text{SiMe}_3)_2$ [23] are significantly distorted from octahedral geometry with the latter complex being particularly distorted, its structure being described as "a pseudo-bicapped tetrahedron with the trimethylsilyl groups as capping ligands" [23]. The most striking feature of this complex is the 141.2(1) $^\circ$ angle between

the two CO trans ligands instead of the 180° expected for a regular octahedron. Also, the Si-Fe-Si angle is 111.8(1)°. The cis-Fe(CO)₄(SnPh₃)₂ complex is similarly distorted with an angle between trans CO groups of 159.6(4)°, and an Sn-Fe-Sn angle of 95.95°. The above distortions provided support for the possibility that rearrangement occurs through a bicapped-tetrahedral intermediate. The authors further showed that this rearrangement involved a cis to trans to cis sequence where the carbonyls become equivalent in the trans isomer.

The crystal structures of Cr(CO)₂(CX)[(MeO)₃P]₃ (X = S, Se), described in Chapter 2, exhibit no marked distortions of the magnitude reported for cis-Fe(CO)₄(SiMe₃)₂ or cis-Fe(CO)₄(SnPh₃)₂. All the angles between trans ligands are approximately 174 ± 1° for both complexes. On this basis, rearrangement by a bicapped-tetrahedron mechanism would not appear to be favoured.

Chapter 4

Kinetic Investigations of Arene Labilization in (η -Arene)- $\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{O}, \text{S}, \text{Se}$) Complexes

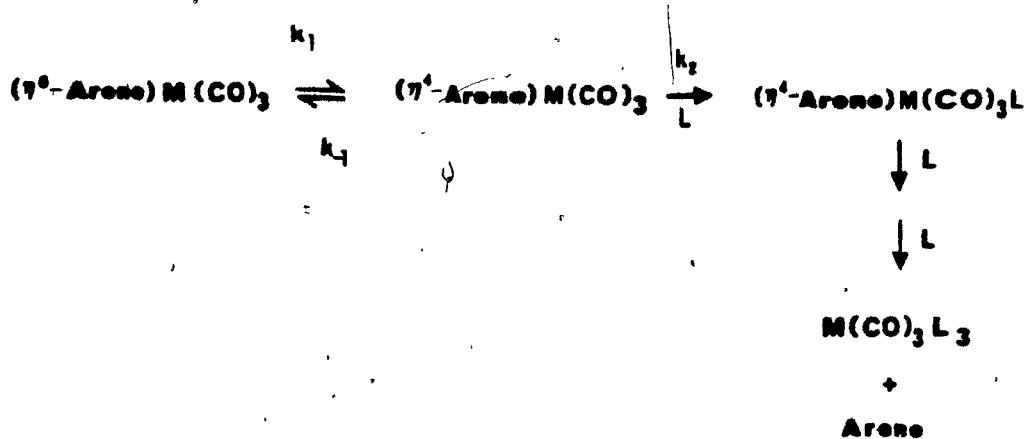

4.1 Introduction

The study of arene labilization in Group VIB metal tricarbonyl complexes has been of considerable interest for many years [1-8], and the mechanism of arene displacement reactions remains under investigation to date [9-11]. Such interest stems from the importance of these complexes in catalytic hydrogenation [5,12] as well as the potential utility of arene exchange processes in the liberation of arenes from such complexes following their derivatization by, for example, Friedel-Crafts reactions [12].

Arene and triene displacement from $(\eta\text{-Arene})\text{M}(\text{CO})_3$ and $(\text{cht})\text{M}(\text{CO})_3$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$) by a monodentate ligand L [$\text{L} = (\text{RO})_3\text{P}, \text{R}_3\text{P}, \text{RCN}, \text{R}_n\text{Cl}_{3-n}\text{P}$ ($n = 1, 2$; $\text{R} = \text{alkyl or aryl}$)] has been reported [2-7] to yield fac- $\text{M}(\text{CO})_3\text{L}_3$. Kinetic investigations of arene displacement reactions of $(\eta\text{-Arene})\text{M}(\text{CO})_3$ ($\text{M} = \text{Mo}, \text{W}$) [2,3,5] and $(\eta\text{-naphthalene})\text{Cr}(\text{CO})_3$ [5] complexes revealed that they follow a second-order rate equation, first order with respect to both the complex and the attacking ligand. In the case of the $(\text{cht})\text{M}(\text{CO})_3$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$) complexes, initial studies involving cht displacement by

$(MeO)_3P$ indicated that these reactions also follow a second-order rate law, first order with respect to the complex and with respect to the attacking ligand [3]. In later studies, employing RCN (R = alkyl and aryl) as entering ligand, the reaction was found to be second order in the case of Cr but third order for Mo and intermediate between second and third order for W [6].

A mechanism for arene displacement reactions of this type was first proposed by Zingales *et al.* [1] in their study of arene substitution by $R_nCl_{3-n}P$ ($n = 1, 2$; R = alkyl or aryl) in $(\eta\text{-Arene})Mo(CO)_3$ complexes, and has been widely accepted. In a recent kinetic investigation of arene exchange and arene displacement reactions, Traylor *et al.* [10] demonstrated that this same mechanism can account for the observed kinetic behaviour of both arene displacement and arene exchange, as well as catalyzed arene exchange, reactions of $(\eta\text{-Arene})Cr(CO)_3$. The mechanism involves a slippage process whereby the ring initially undergoes a transformation from an η^6 to an η^4 bonding mode prior to attack by the incoming nucleophile.

If the rate constant for the reverse process, k_{-1} , were small, then the reaction would be zero order with respect to the incoming ligand. Since this is not the case in any of the arene displacement reactions studied, where no dissociative term has been found, it is assumed that $k_{-1} \gg k_2$. Thus, the arene displacement reactions exhibit a first-order dependence on the concentration of both the incoming ligand and the complex. Subsequent steps leading to total displacement of the arene are rapid, and generally do not contribute to the observed rate. The variation in the reaction order observed for cht displacement from $(cht)M(CO)_3$ ($M = Mo, W$) by nitriles was attributed to the weak nucleophilic strength of the nitriles resulting in comparable rates of nitrile dissociation from and coordination of a second nitrile to the proposed intermediate $(n^4\text{-}cht)M(CO)_3(RCN)$ ($M = Mo, W$) [6].

The above mechanism is consistent with various considerations that have been put forward in the literature regarding the reaction pathways available to complexes of this type. Basolo [13] has stated that "Substitution reactions of 18-electron transition metal organometallic compounds may proceed by an associative mechanism provided the metal complex can delocalize a pair of electrons onto one of its ligands." Muetterties et al. [14] postulated for the reaction of $(bz)ML_3$ complexes with L' that "Mechanistically

a reasonable intuitive scenario would start with an η^6 to η^4 dissociation of the coordinated arene ... An associative mechanism (or an interchange mechanism of associative intimate character) for the attack of an external ligand on η^6 -benzene- ML_3 would seem unlikely.¹⁴ Such a "ring slippage" creates a vacant orbital at the metal, providing a low-energy associative reaction pathway [14]. Muettterties et al. also stated that the resulting η^4 complex should be sensitive to steric effects induced by either a substituent on the ring or on the incoming nucleophile, and that the η^4 ring must undergo distortion from planarity to allow the incoming ligand access to the metal. They estimated that the energy required to bend the coordinated benzene ring in $(bz)Cr(CO)_3$ from planarity, as well as to distort the $Cr(CO)_3$ group to facilitate acceptance of the incoming ligand, is about 15 kcal mol⁻¹ [14].

In this chapter, an investigation of the kinetics of arene displacement from $(\eta\text{-Arene})Cr(CO)_2(CX)$ ($X = S, Se$) complexes by tertiary phosphites is reported. This represents the first kinetic study of an organometallic selenocarbonyl derivative, ever undertaken. These studies will provide a quantitative measure of the influence of the chalcocarbonyl ligands on arene lability in these complexes.

4.2 Experimental

4.2.1 Sources of Materials

All (η -Arene)Cr(CO)₂(CX) (X = O, S, Se) complexes and (cht)Cr(CO)₃ were purified by TLC prior to use, and their purity was established by the absence of any superfluous peaks in the ν (CO) region of their FT-IR spectra. Trimethyl- and triphenylphosphite, gold label purity (99+%), triethylphosphite, 99% purity, and trimethylphosphate, gold label purity (99+%), were purchased from Aldrich Chemical Co. and were used without further purification. Tri-n-butyl- and tricyclohexylphosphite were obtained from Strem Chemicals. The phosphites were handled under an atmosphere of prepurified N₂ (3 ppm O₂, 5 ppm H₂O). ³¹P NMR spectra of the phosphites over a full spectral window (40,000 Hz) were measured periodically to verify the absence of any phosphorus-containing impurities. Fresh bottles of phosphite (100 ml) were used every third run or within four days of opening the bottle. The methylcyclohexane (99%) solvent was distilled over sodium under nitrogen and transferred under nitrogen to a nitrogen-purged flask containing a weighed amount of the complex. Dichloroethane (99%) was distilled over calcium chloride under nitrogen and transferred according to the above procedure.

4.2.2 Preparation of Samples

All procedures were performed under a nitrogen atmosphere in a stainless steel glove box which was periodically evacuated and purged with nitrogen. The nitrogen purge was maintained throughout the sample preparation procedure. Typically two samples of 1.40 mg of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2\text{CX}$ ($\text{X} = \text{O}, \text{S}, \text{Se}$) were weighed out on a Cahn electrobalance (precision ± 0.01 mg) and were transferred to two 25-ml volumetric flasks fitted with hollow Teflon plugs capped with rubber septa. The flasks were then purged with nitrogen prior to transferring the solvent. A third flask was filled with distilled solvent under nitrogen. The three flasks were then transferred to the glove box, together with at least four matched quartz cuvettes (1-cm pathlength) fitted with Viton O-rings, the bottle containing the phosphite ligand and two 1-ml ($\pm 1\%$) Hamilton syringes with Teflon barrels. A measured volume of the solution was syringed out and replaced by an equal volume of phosphite (providing $[L] 800-3000$ times in excess of $[(\eta\text{-Arene})\text{Cr}(\text{CO})_2\text{(CX)}]$). The flask was then capped and shaken vigorously. One cuvette was filled with the solution containing only $(\eta\text{-Arene})\text{Cr}(\text{CO})_2\text{(CX)}$. Another cuvette was filled with the solution containing both phosphite ligand and complex. The other two cuvettes were filled with pure solvent.

The cuvettes were transferred to a Varian Cary 210 UV-vis spectrophotometer equipped with a thermostatted multi-sample support assembly. Due to the elevated temperatures used ($> 45^{\circ}\text{C}$), two water-cooled jackets (supplied by Varian) were placed on either side of the heating assembly to protect the spectrophotometer optics. The time to equilibrate the cuvettes to the designated kinetic run temperature was 17 min. The kinetic run temperature was determined by placing a calibrated thermocouple wire into a cuvette containing methylcyclohexane under the exact conditions of the kinetic run. No loss of solvent was observed up to 72 h at 85°C . The spectrometer was equipped with a cell programmer accessory and was interfaced to an Apple II+ computer (64K). The programs "Master Scan Storage" and "Master Kinetic Storage", both supplied by Varian, were utilized to collect and store wavelength scans (500–280 nm) and absorbances at three selected wavelengths, respectively, at programmed time intervals. Usually a run was between 10 h and 48 h in duration and the data acquisition was triggered every 10 or 15 min. The data acquired for the disappearance of the starting material were analyzed, yielding k_{obsd} , using the "Advanced Order Kinetic Program" supplied by Varian and based on a multiple-linear-regression program described in Reference 15.

Least-squares analysis for the calculation of k_1 and k_2

and the activation parameters was performed with no data smoothing or data averaging, using a "Curve Fitter" program written by P.K. Warm for Interactive Microware, Copyright (C) 1980.

4.3 Results and Discussion

The kinetics of arene displacement in (*n*-Arene)Cr(CO)₂(CX) (X = S, Se) by trialkyl- and triarylphosphites were monitored by UV-vis spectroscopy. All reactions exhibited one isosbestic point (Figure 4.1), indicating only one process was taking place, with no side reactions. The rate of reaction under pseudo-first-order conditions (800-3000 fold excess of tertiary phosphite) was determined from the decrease in absorbance of the starting material with time. The pseudo-first-order rate constants, k_{obsd} , were determined by a multiple-linear-regression program [15].

The dependence of reaction rate on ligand concentration was investigated for the reaction of (bz)Cr(CO)₂(CX) (X = S, Se) with trimethylphosphite (Tables 4.1 and 4.2). Plots of k_{obsd} vs. $[(\text{MeO})_3\text{P}]$ were linear for the range of concentrations used (Figure 4.2). Least-squares analysis was used to fit the data to the equation $k_{\text{obsd}} = k_1 + k_2[(\text{MeO})_3\text{P}]$. The value of k_2 was obtained from the slope. For both complexes the intercept was zero within the standard deviation

^aA least-squares fit of these data to the equation

$k_{obsd} = k_1 + k_2[(MeO)_3P]$ yields $k_1 = (1.2 \pm 1.8) \times 10^{-6} s^{-1}$,
 $k_2 = (1.39 \pm 0.04) \times 10^{-4} M^{-1} s^{-1}$; $r = 0.99$.

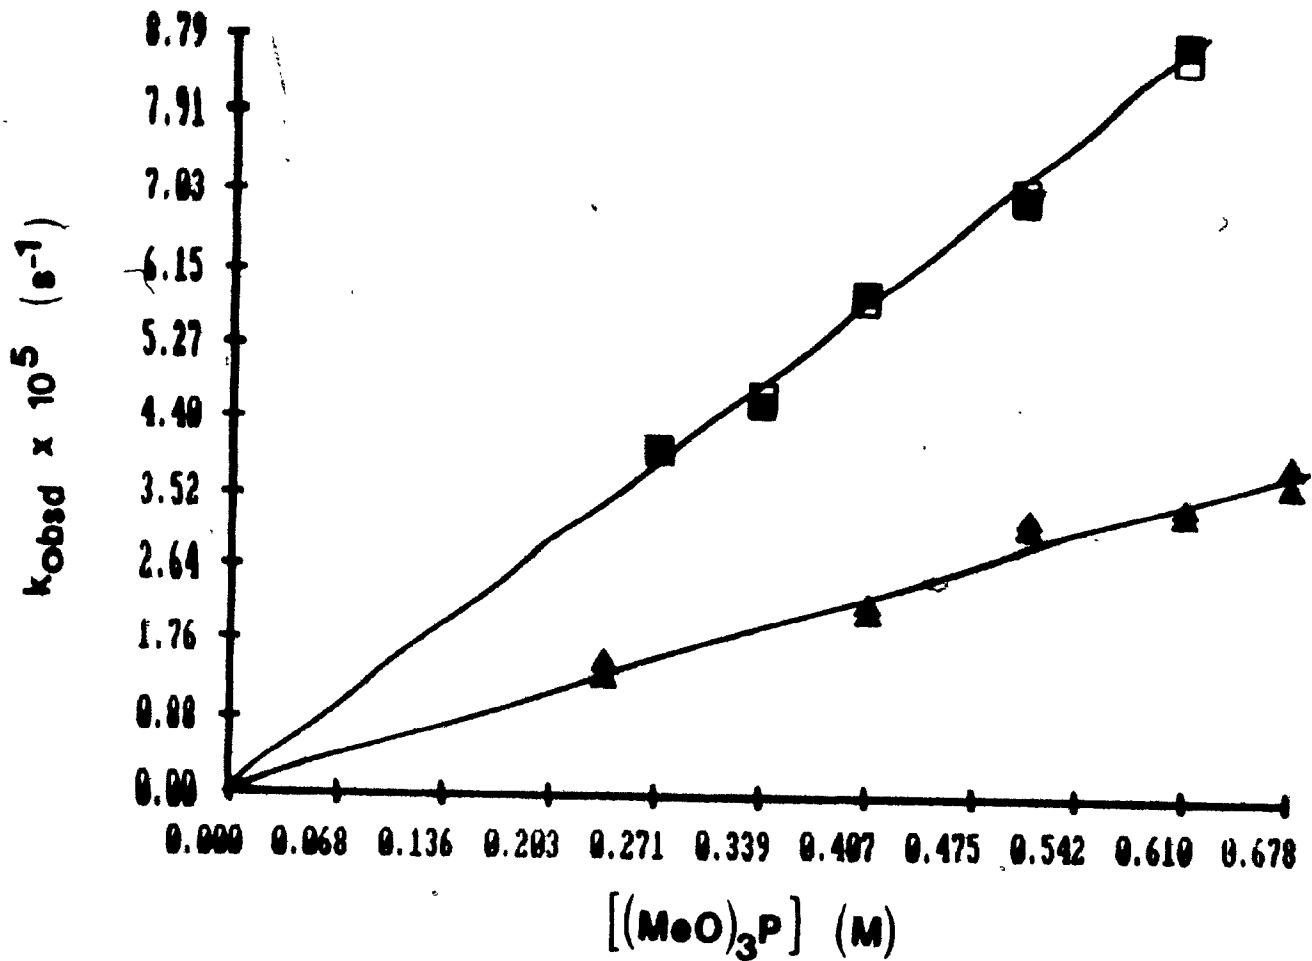

Figure 4.2. Plots of k_{obsd} vs. $[(\text{MeO})_3\text{P}]$ for the reaction of $(\text{bz})\text{Cr}(\text{CO})_2(\text{CX})$ with $(\text{MeO})_3\text{P}$: Δ , $X = \text{S}$; \blacksquare , $X = \text{Se}$.

and hence k_1 is zero (Tables 4.1 and 4.2). Therefore, the rate of the reaction can be accurately represented by the rate expression:

$$\frac{d[(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})]}{dt} = k_2[(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})][(\text{MeO})_3\text{P}] \quad (4.1)$$

So, $k_2 = k_{\text{obsd}}/[(\text{MeO})_3\text{P}]$ for the range of $(\text{MeO})_3\text{P}$ concentrations used. It is of interest to note that all of the kinetic investigations reported to date on arene and triene displacement from chromium(0) tricarbonyl derivatives by a range of both strong and weak nucleophiles or another arene or triene did not reveal any contribution from a dissociative term.

The activation parameters were obtained by least-squares analysis of the kinetic data for the variation of k_2 with temperature (Tables 4.3 and 4.4) employing the following equation:

$$k_2 = (kt/h)e^{\Delta S^\ddagger/R} e^{-\Delta H^\ddagger/RT} \quad (4.2)$$

The enthalpy of activation was calculated from the slope of the usual $\ln k_2$ vs. $1/T$ plot and is small and positive while the entropy of activation is large and negative in both the thiocarbonyl and the selenocarbonyl case (Figure 4.3). Thus the rate-determining step appears to involve a

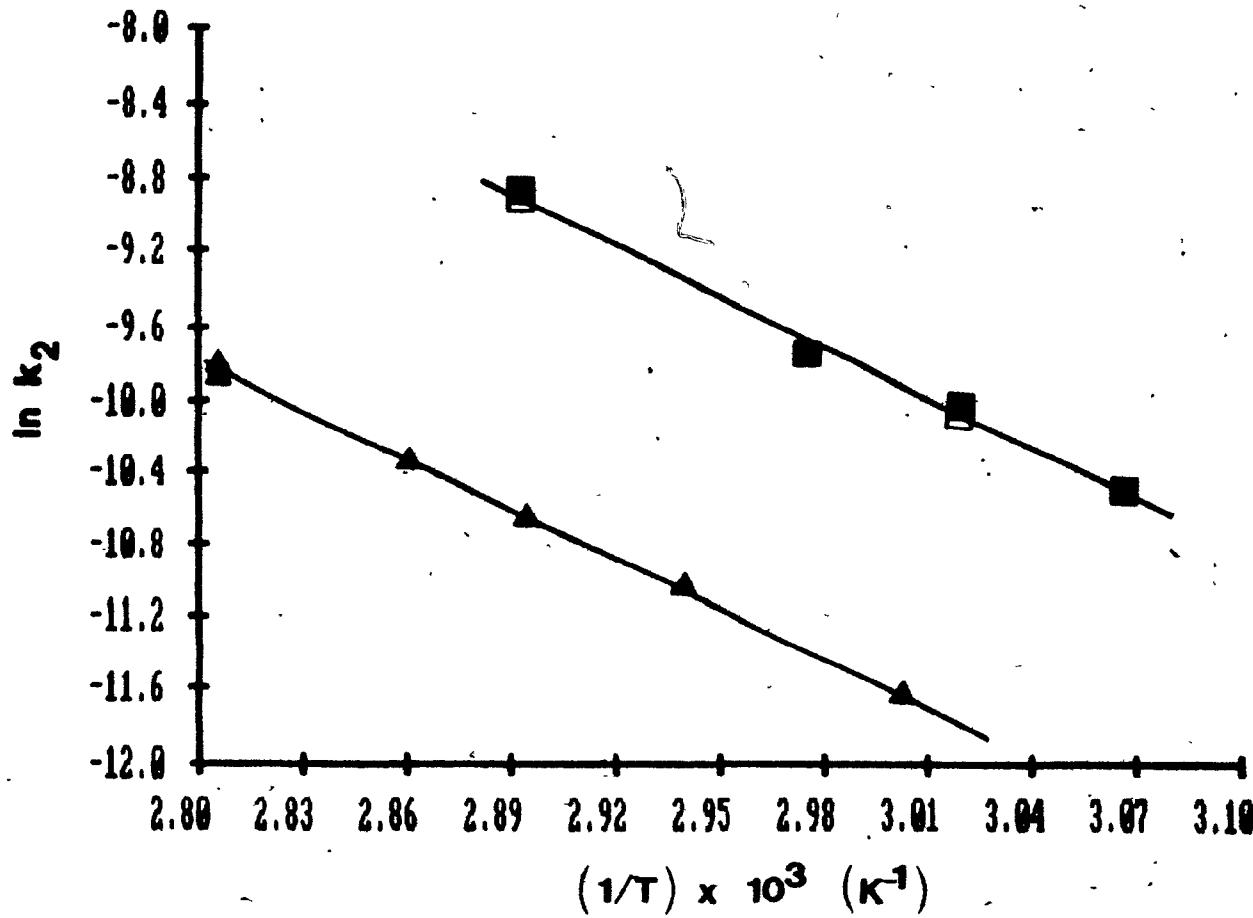

Figure 4.3. Plots of $\ln k_2$ vs. $1/T$ for the reaction of $(\text{bz})\text{Cr}(\text{CO})_2(\text{CX})$ with $[(\text{MeO})_3\text{P}]$: Δ , $X = \text{S}$; \blacksquare , $X = \text{Se}$. Least-squares analysis of these data yields $\Delta H^\ddagger = 17.7 \pm 0.4 \text{ kcal mol}^{-1}$ and $\Delta S^\ddagger = -28 \pm 1 \text{ cal mol}^{-1} \text{ deg}^{-1}$ for $X = \text{S}$ and $\Delta H^\ddagger = 17.9 \pm 1.3 \text{ kcal mol}^{-1}$ and $\Delta S^\ddagger = -24 \pm 2 \text{ cal mol}^{-1} \text{ deg}^{-1}$ for $X = \text{Se}$.

bimolecular associative process. Similar activation parameters (Table 4.5) were obtained in previous kinetic studies of the reactions of $(\eta\text{-Arene})M(CO)_3$ ($M = Mo, W$) with a ligand L [$L = (MeO)_3P, R_nCl_{3-n}P$ ($n = 0-2$; $R = \text{alkyl or aryl}$)] [1,2,4] and of $(cht)M(CO)_3$ ($M = Cr, Mo, W$) with $(MeO)_3P$ [3]. These data were interpreted in terms of the mechanism described in Section 4.1, involving a partial displacement of the η^6 -coordinated arene or triene to an η^4 -bonding mode prior to attack by the ligand. This same mechanism may, therefore, be postulated to account for the kinetic data reported here for arene displacement from $(\eta\text{-Arene})Cr(CO)_2(CX)$ ($X = S, Se$).

Comparison of the activation parameters in Figure 4.3 reveals that the entropy of activation is the factor governing the difference in reactivity between $(bz)Cr(CO)_2(CS)$ and $(bz)Cr(CO)_2(CSe)$, while the enthalpies of activation are similar for the two complexes. That ΔS^\ddagger is more negative for $(bz)Cr(CO)_2(CS)$ than for $(bz)Cr(CO)_2(CSe)$ may imply a closer proximity of the arene and the incoming ligand to the metal in the transition state in the thiocarbonyl complex, leading to more unfavourable steric interactions. This possibility is supported by the longer metal-arene bond in $(mbz)Cr(CO)_2(CSe)$ compared to $(mbz)Cr(CO)_2(CS)$, established by X-ray diffraction studies of these complexes [16]. Furthermore, the P-Cr bond lengths observed in the crystal

structure of $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$ [especially for the P-Cr bond trans to the CSe ligand (Table 2.4)] are longer than the corresponding bond lengths in the thiocarbonyl analogue (Table 2.2). These longer P-Cr bond distances suggest a less significant steric effect due to the incoming ligand during bond formation in the activated complex in the case of the selenocarbonyl derivative.

A second factor that may be considered in accounting for the observed difference in ΔS^\ddagger is the ease of distortion of the arene ring. The complexes $(\eta\text{-}1,2,3\text{-trimethoxybenzene})\text{Cr}(\text{CO})_3$ and $(\eta\text{-diethylaniline})\text{Cr}(\text{CO})_3$ have been found to exhibit a greater degree of arene lability than would be anticipated on the basis of the metal-arene bond strengths in these complexes [18]. Recently, crystal structure investigations of these complexes [19] revealed significant distortions of the arene from a planar geometry in both cases; it has been proposed [19] that these distortions allow an incoming nucleophile greater accessibility to the metal centre, thereby effecting an enhancement in ring lability. Analysis of the crystal structure data for the complexes $(\text{mbz})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{O}, \text{S}, \text{Se}$) [16] revealed minor variations in the metal-C(ring) distances. No evidence was found for arene distortions of comparable magnitude to those observed for $(\eta\text{-diethylaniline})\text{Cr}(\text{CO})_3$ or $(\eta\text{-}1,2,3\text{-trimethoxybenzene})\text{Cr}(\text{CO})_3$. However, the lack of

ring distortion in the solid-state structure does not preclude the possibility that the lower entropy of activation in the arene displacement reaction for $(bz)Cr(CO)_2(CSe)$ relative to the thiocarbonyl analogue may be due to a more facile distortion of the arene ring in the activated state.

Subsequent to establishing the rate expression for arene displacement, an examination of the effect on arene lability of substituents on the ring was undertaken. Increasing the number of methyl groups on the ring generally decreases the rate of the reaction (Table 4.6). The reaction of $(\eta\text{-mesitylene})Cr(CO)_2(CS)$ with $(MeO)_3P$ was too slow to measure accurately so that only the rate for reaction with the much more nucleophilic $(n\text{-BuO})_3P$ (see Table 4.7) is given in Table 4.6. No attempts were made to investigate reactions of arenes with more than three electron-donating substituents because these would be too slow to monitor with any degree of accuracy. The results in Table 4.6, including the anomalously fast rate of \underline{o} -xylene displacement, are in line with kinetic studies reported by other groups who have investigated the arene displacement reactions of $(\eta\text{-Arene})M(CO)_3$ ($M = Mo, W$) [1,2,4]. The decrease in reaction rate upon addition of electron-donating substituents on the arene ring may be attributed to the strengthening of the metal-arene bond resulting from the increased electron density at the ring. Steric effects may also contribute to the

observed trend in that the substituents on the ring may hinder the attack of the nucleophile at the metal centre.

The presence of electron-withdrawing groups on the ring enhances ring lability (Table 4.6) in accord with the ability of these groups to decrease the electron density available at the ring for bonding to the metal. The presence of both an electron-donating and an electron-withdrawing group on the ring gives an intermediate rate for the ring displacement reaction, while the presence of a second electron-withdrawing group in the para position has a cooperative effect in enhancing the rate of displacement.

In order to probe further the relationship between the rate of arene displacement and metal-arene bond strength, force constant calculations for the metal-arene stretching vibrations in these complexes would be in order. These force constants can really only be acquired through detailed normal coordinate calculations [20]. Fortunately, however, the CO stretching force constants are known to reflect the electron density at the metal in complexes of this type and can be correlated with the electron-donating/withdrawing properties of the substituents on the arene [21]. Therefore, the rate constants for arene displacement for a series of (η -Arene)Cr(CO)₂(CS) complexes as a function of the CO stretching force constants of the complexes are plotted in Figure 4.4. The latter were calculated from the positions

($\tilde{\nu}_1$, $\tilde{\nu}_2$) of the two $\nu(\text{CO})$ peaks in the IR spectrum according to the energy-factored force field approximation:

$$k_{\text{CO}} = (\lambda_1 + \lambda_2)/2\mu \quad (4.3)$$

where $\lambda_i = 1/(4\pi^2 c^2 \tilde{\nu}_i^2)$, c is the speed of light and μ is the reduced mass of CO. A least-squares analysis of these data yields a linear relationship between the CO force constant and $\ln k_{\text{obsd}}$ (Figure 4.4) ($r = 0.98$, for compounds III-VIII). However, the points corresponding to the dimethylaniline and *p*-dimethoxybenzene complexes exhibit anomalous behaviour ($r = 0.11$ for compounds III-X). The same observation has been reported by Pidcock *et al.* in their studies of arene displacement from $(\eta\text{-Arene})\text{M}(\text{CO})_3$ ($\text{M} = \text{Mo, W}$) [2,4]. This may be proposed to result from distortions of the arene from a planar geometry, as observed for the diethylaniline and trimethoxybenzene chromium tricarbonyl derivatives discussed above. Thus, in the thiocarbonyl complexes studied here, a similar distortion in conjunction with the labilizing effect of the thiocarbonyl ligand can explain the anomalously fast rate of arene displacement from $(\eta\text{-p-dimethoxybenzene})\text{Cr}(\text{CO})_2(\text{CS})$ and $(\eta\text{-dimethylaniline})\text{Cr}(\text{CO})_2(\text{CS})$.

The rate of ring displacement can also be affected if the carbonyl groups are replaced by weaker π -acceptors or

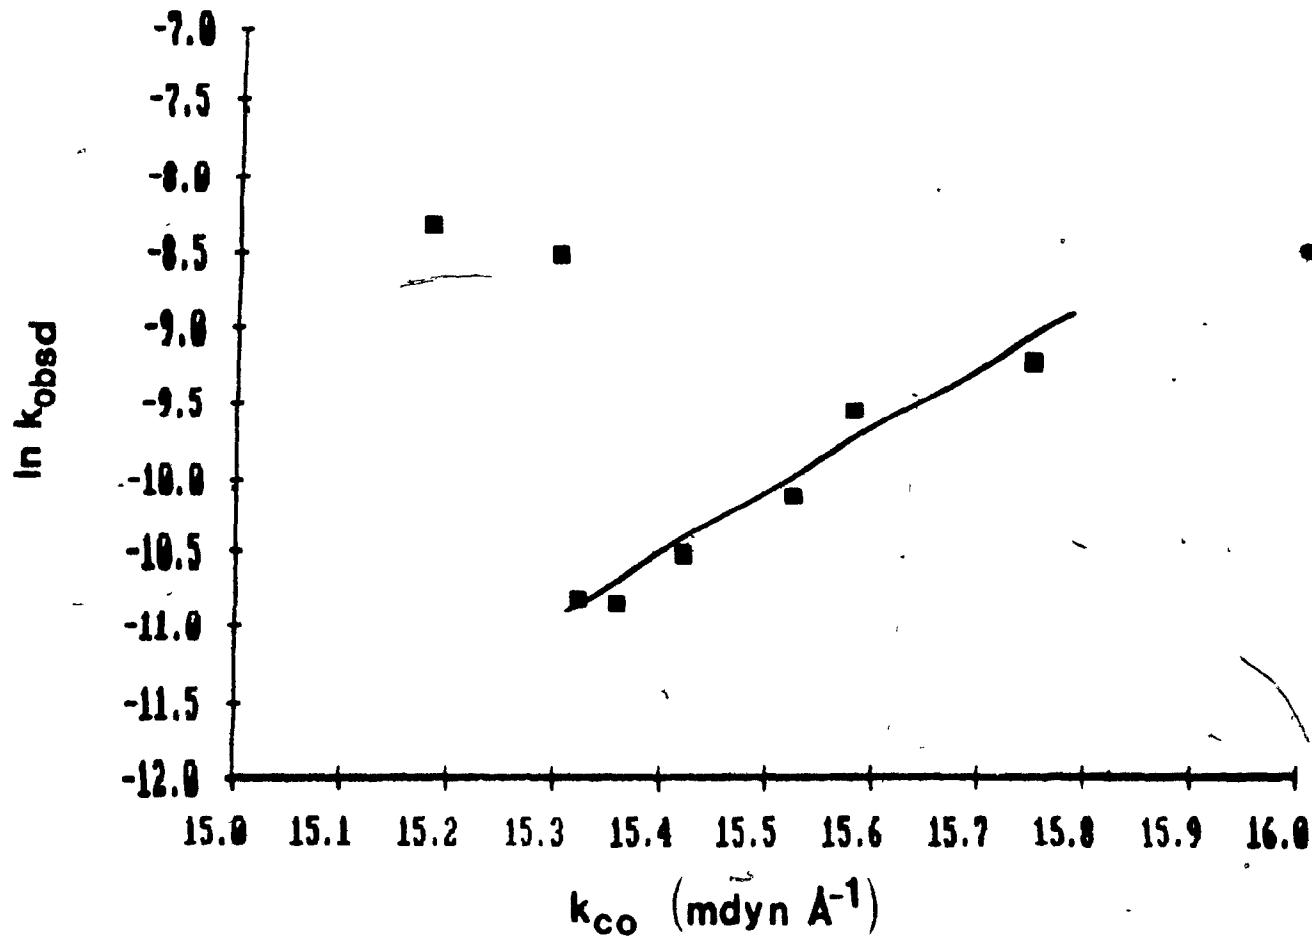

Figure 4.4. Plot of $\ln k_{obsd}$ values for the reactions of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CS})$ complexes with $(\text{MeO})_3\text{P}$ vs. the carbonyl stretching force constants (k_{CO}) of the arene complexes. The following k_{CO} values for the complexes given in Table 3.6 were calculated from Eq. 4.3: III, 15.32; IV, 15.36; V, 15.42; VI, 15.52; VII, 15.58; VIII, 15.75; IX, 15.30; X, 15.18 mdyn Å⁻¹.

stronger σ -donors. The reactivity of $(mbz)Cr(CO)_2(CS)$ was compared with that of $(mbz)Cr(CO)(CS)[(PhO)_3P]$. The monocarbonyl complex is seen to be unreactive over a period of 24 h at 87°C while $(mbz)Cr(CO)_2(CS)$ reacts at 60°C in half the time. The lack of reactivity may be attributed to two factors. First, the weaker π -accepting and stronger σ -donating properties of the tertiary phosphite relative to CO increase the electron density at the metal available for π -backbonding to the arene, thus strengthening the metal-arene bond. Second, a steric effect may also contribute in that the phosphite may block the access of the attacking nucleophile to the metal. The decreased catalytic activity of $(\eta\text{-Arene})Cr(CO)_2(R_3P)$ ($R = Ph, OPh$) compared to $(\eta\text{-Arene})Cr(CO)_3$ has been attributed to the above factors [22,23].

Table 4.7 shows the effect observed with the variation in the steric and nucleophilic character of the attacking ligand. The reaction rate increases with increasing nucleophilicity for ligands of comparable size (similar cone angles) and decreases with increasing size of the ligand. This trend has also been reported in the study of arene displacement from $(\eta\text{-Arene})Mo(CO)_3$ complexes [1]. Thus, the rate of arene displacement by tertiary phosphite decreases in the order $(n\text{-BuO})_3P > (EtO)_3P > (MeO)_3P > (PhO)_3P > (C_6H_{11}O)_3P$ [no reaction was observed for $(C_6H_{11}O)_3P$].

(bz)Cr(CO)₂(CSe) was seen with the addition of (Me)₃PO (Table 4.8). Decomposition was observed in the absence of tertiary phosphite. The strong labilizing effect of oxygen donor bases has been noted previously [24]. Trialkylphosphine oxides have been used in various systems to catalyze CO substitution [25,26] and have been reported to enhance ring lability in (η -Arene)Mo(CO)₃ [2]. In the present case, the catalytic enhancement can be postulated to involve nucleophilic attack on the metal by the oxygen, forming (η^4 -Arene)Cr(CO)₂(CSe)(+O=P(Me)₃).

The kinetic study of arene displacement in (η -Arene)Cr-(CO)₂(CSe) by (MeO)₃P was also performed in dichloroethane ($k_2 = 3.56 \times 10^{-5} M^{-1} s^{-1}$ at 53.0°C). The reaction rate is slightly higher than that observed in methylcyclohexane ($k_2 = 2.72 \times 10^{-5} M^{-1} s^{-1}$ at 53.0°C) providing evidence that the activated complex may be polar in character and possibly solvent stabilized [1].

No kinetic data are available for arene displacement from (η -Arene)Cr(CO)₃ complexes due to their slow reactivity. Attempts were made in this study to measure the kinetics of arene substitution reactions of arene chromium tricarbonyls under rigorous conditions (83.3°C, [(MeO)₃P]:[$(\eta$ -Arene)Cr(CO)₃] = 3000:1) and even for (η -dimethyl-aniline)Cr(CO)₃, one of the most reactive tricarbonyl complexes, after heating for 48 h there was no decrease in its

UV-visible absorbance nor was there any evidence of product formation. Under the same conditions, (η -dimethyl-aniline)Cr(CO)₂(CS) reacts completely in less than 3 h. Clearly, the effect of the thiocarbonyl ligand on the reactivity of the arene chromium carbonyl complex is quite significant. From these data it can be seen that even placing the most electron-withdrawing substituent on the arene ring in a tricarbonyl complex would not result in a labilizing effect on the metal-arene bond as great as that resulting from the substitution of one carbonyl group by a thiocarbonyl ligand. Furthermore, the effect of substitution of a selenocarbonyl ligand in place of a carbonyl ligand has even more dramatic effects on arene lability. These first kinetic results for a selenocarbonyl complex reported here have provided a quantitative measure of the increased reactivity of (η -Arene)Cr(CO)₂(CSe) complexes with respect to their thiocarbonyl counterparts, the enhancement in ring lability being close to fivefold at 50°C.

Table 4.9 shows the rates recorded for various ring displacements from Group VIB metal complexes by (MeO)₃P. Ring lability decreases in the order (cht)Mo(CO)₃ > (cht)W(CO)₃ >> (cht)Cr(CO)₃ >> (bz)W(CO)₃ > (bz)Cr(CO)₂(CSe) > (bz)Cr(CO)₂(CS) > (bz)Cr(CO)₃. The reactivity of the cycloheptatriene derivatives has been attributed to the relative weakness of the bonds between the metal and the

ring carbons adjacent to the methionine group in the cht ligand while the relative rates down the metal triad have been correlated to the ring-metal force constants and metal size [3].

A striking feature of the arene displacement reactions of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S}, \text{Se}$) complexes is the involvement of an isomerization process, as evidenced by the predominant formation of the mer I isomer rather than the fac isomer which is the major product in the cht displacement from $(\text{cht})\text{Cr}(\text{CO})_3$. It has been shown in Chapter 3 that in the temperature range at which the reactivity of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ with $(\text{MeO})_3\text{P}$ has been studied the fac and mer I isomers of the products, $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$, are in equilibrium, with the mer I isomer predominating ($K_{\text{eq}} = 5$). Furthermore, comparison of the rates measured for the fac \rightarrow mer I isomerization process with results of the kinetic studies reveals that the isomerization of fac- $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ is at least an order of magnitude faster than the rate of reaction to form $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ at all temperatures studied. It is therefore likely that fac- $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ is formed first in the reaction of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ with $(\text{MeO})_3\text{P}$, and then isomerizes to the mer I isomer. However, the possibility that isomerization also takes place in the intermediate steps of the reaction prior to the formation of the final product cannot be

ruled out. Some evidence against this latter possibility was obtained by monitoring the reaction of $(bz)Cr(CO)_2(CSe)$ with $(PhO)_3P$ by ^{31}P NMR spectroscopy. fac- $Cr(CO)_2(CSe)-[(PhO)_3P]_3$ was detected in a higher concentration than the mer I isomer in the initial stages of the reaction with $(PhO)_3P$ (Figure 4.5), while the final product was predominantly the mer I isomer. This observation suggests that rearrangement to the thermodynamically more stable mer I isomer occurs subsequent to the formation of the kinetically expected fac product. The initial detection of the fac isomer with the $(PhO)_3P$ ligand but not with $(MeO)_3P$ may be the result of a slower rate of isomerization in the former case due to steric effects imposed by the bulky phenoxy substituents.

The reactions of the tridentate ligands triphos-U and triphos with $(\eta\text{-Arene})Cr(CO)_2(CX)$ afford fac-(L-L-L)- $Cr(CO)_2(CX)$ complexes in quantitative yield, giving added support to the hypothesis that the fac product is formed first in the reactions with the monodentate phosphite ligands. If the formation of the mer I isomer in the latter cases was the result of isomerization of an intermediate in the reaction pathway, then reaction with tridentate ligands might be expected to result either in bridging of the tridentate ligand across the metal or, if such a structure were unfavourable, in a low, rather than quantitative yield of

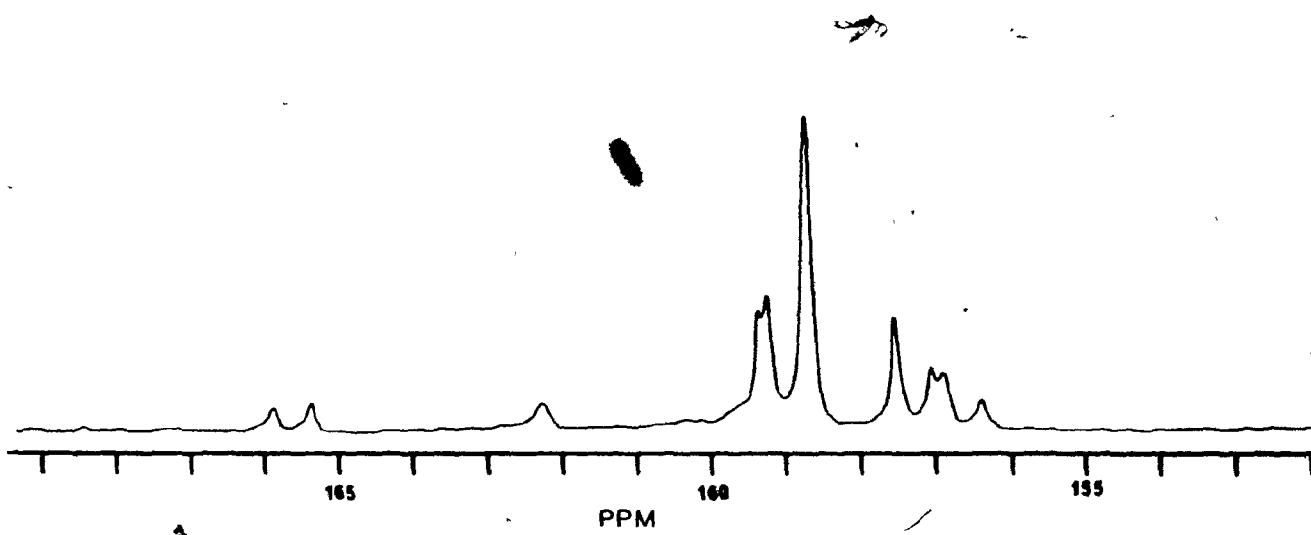

Figure 4.5. ^{31}P NMR spectrum recorded at $t = 60$ min of the reaction of $(\text{bz})\text{Cr}(\text{CO})_2(\text{CSe})$ with $(\text{PhO})_3\text{P}$ at 60°C , revealing the initial formation of $\text{fac-Cr}(\text{CO})_2(\text{CSe})[(\text{PhO})_3\text{P}]_3$. Conditions: obtained on a Varian XL-300 FT spectrometer operating at 121.42 MHz; ^1H -decoupled; sweep width = 30,000 Hz; offset = 12,400 Hz; flip angle = 40°, repetition time = 0.5 s; number of scans = 400.

the fac product. However, the high effective local concentration of incoming ligand after coordination of the first phosphorus atom of the tridentate ligand to the metal would not provide much time for rearrangement of an intermediate to occur.

It is of interest to note that in earlier studies of arene displacement from $(\eta\text{-Arene})\text{M}(\text{CO})_3$, kinetic investigations of the reactions of $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ with ligands L were not undertaken because they yielded products other than the expected fac- $\text{Cr}(\text{CO})_3\text{L}_3$. Although we were unable to obtain kinetic data for arene displacement from $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ by $(\text{MeO})_3\text{P}$, we were able to characterize the products of these reactions as mixtures of mer- and fac- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ with the mer isomer predominant. Furthermore, the rate measured for fac + mer isomerization of this complex (Chapter 3) is faster by at least three orders of magnitude than the rate of arene displacement in the $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ systems (Table 4.9). Therefore, just as for the thio- and selenocarbonyl analogues, the formation of predominantly mer- $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ in the reaction of $(\eta\text{-Arene})\text{Cr}(\text{CO})_3$ with $(\text{MeO})_3\text{P}$ may be attributed to isomerization of the expected fac isomer at a much faster rate than its rate of formation. In the case of the reaction of $(\text{cht})\text{Cr}(\text{CO})_3$ with $(\text{MeO})_3\text{P}$, the reaction rate at, for example, 50°C [3] is eight times faster (for $[(\text{MeO})_3\text{P}] = 1 \text{ M}$)

than the rate of isomerization of $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$, at this temperature, thus accounting for the formation of the fac isomer.

4.4 Concluding Remarks

The studies of arene labilization for the thiocarbonyl complexes were initially undertaken to elucidate why such complexes lack the catalytic activity exhibited by the corresponding tricarbonyl complexes. The results described here demonstrate that the products of arene displacement reactions of the thiocarbonyl complexes exhibit a faster rate of intramolecular isomerization than the parent tricarbonyls. The rapid occurrence of rearrangement processes of the type observed in this study would not afford the necessary intermediates required for catalytic activity to take place, since it has been shown that the fac configuration is crucial in effecting hydrogenation through the mechanisms outlined in Chapter 1. In addition, the crystal structure of $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$ obtained provided evidence for a very large amount of electron density on the thiocarbonyl ligand - the C-S bond distance approximating that of a bridging CS group. Nucleophilic attack by the sulfur atom of the thiocarbonyl ligand has been reported [27] for complexes exhibiting low $\nu(\text{CS})$ frequencies and, accordingly, long C-S bond lengths. Since hydrogenation studies take place in the presence of donor solvents, $\text{Cr}(\text{CO})_2(\text{CS})\text{L}_3$

species are probably formed. It is likely that the electron density on the CS ligand in such species is sufficient to cause the thiocarbonyl to act as a nucleophile leading to side reactions or autodecomposition.

Although, to date, no catalytic studies have been performed with selenocarbonyl complexes, their catalytic activity will almost certainly be the same as that of the thiocarbonyl complexes because of the similar reactivities of these chalcocarbonyl derivatives.

**Applications of FT-IR Spectroscopy
and Metal Chalcocarbonyl Chemistry
in Biological Systems**

Chapter 5

Applications of FT-IR Spectroscopy in the Study of Biological Systems

In the 1984 May-June issue of Applied Spectroscopy, Jakobsen announced in a guest editorial the recent formation of the first National Center for Biomedical FT-IR Spectroscopy. The logo for the center is an interferogram joining

the double helix structure of DNA with a caduceus to represent the bridge of molecular spectroscopy between biology and medicine. He stated the functions of the center are "1) to advance the state-of-the-art of FT-IR; 2) to demonstrate new applications of FT-IR in both biology and medicine; 3) to collaborate with scientists outside the Center and provide them with spectroscopy information useful to their research; 4) to spread the word to the scientific community about the use of FT-IR in this research; and 5) to train

scientists in the use of FT-IR for biomedical purposes."

In the past, IR spectroscopy has been of limited usefulness in the study of complex biological systems for the following reasons:

(a) Spectra of dry protein could not provide a direct correlation to in vivo biological processes. Therefore, in order to simulate biological conditions, spectra of biological systems were generally measured in H₂O (or D₂O) solutions, resulting in a loss of large regions of the spectra because of the strong H₂O (D₂O) absorptions. The use of D₂O posed additional problems because of hydrogen-deuterium exchange which often causes conformational changes.

(b) Biological systems generally contain many different proteins, as well as numerous organic species, which can have an interfering effect in the study of the biomolecule or the biological process of interest.

(c) A large number of biologically active species exist in too low concentrations to be detected by dispersive IR spectroscopy.

The advent of FT-IR instrumentation has allowed several orders of magnitude improvement in signal-to-noise (S/N) ratio in relatively short times of data acquisition [1-13] as a result of the multiplex (Fellgett's) and throughput (Jacquinot's) advantages of the FT-IR spectrometer. Digitization of the spectra permits digital absorbance subtraction, thereby eliminating solvent and other interferences.

The following examples illustrate the types of information which have been obtained by FT-IR investigations of biological systems. This survey in part serves to indicate the rather limited extent to which FT-IR spectroscopy has been applied in biological studies. It does not include studies of the FT-IR spectra of isolated small biomolecules or model compounds, which are far more numerous.

The first applications of FT-IR spectroscopy in biological investigations were carried out by Alben and co-workers. An example of this group's work is their study of the nature of carbon monoxide binding and of the molecular binding sites in various hemocyanins [14,15]. Hemocyanins are the oxygen transport proteins in the hemolymph of many molluscs and decapod crustaceans, and reversibly bind oxygen or carbon monoxide with a stoichiometry of one ligand per two copper atoms. Relatively little was known about the ligand binding to copper in these proteins before the FT-IR studies. The IR spectra of the hemocyanin-carbon monoxide complexes of various species show great similarities. They exhibit only one narrow absorption band between 2300 and 1800 cm^{-1} due to bound carbon monoxide. Therefore, only one kind of CO environment appears to exist for each species [16]. The observed narrow half-band width, as compared to half-band widths of carbonyl peaks in solvents of different polarities, suggests that the active site of the copper is

located in a non-polar environment in the protein [14,15]. Also, the observed differences in the absorption maxima [ν (CO)] for carboxyhemocyanin in various species were attributed to differences in the amino acid groups coordinated to the copper binding the carbon monoxide [15].

Alben and his co-workers have also utilized the enhancement of the S/N ratio in FT-IR spectroscopy relative to previous IR spectroscopic methods to examine specific amino acid interactions (e.g., sulfhydryl groups [ν (SH)] of cystine residues of human carboxyhemoglobin) [17]. They showed that the absorbance of the sulfhydryl group is highly sensitive to the state of ligation, and to the tertiary and quaternary structure of the protein, thus, providing a new probe of native hemoglobin structure and its conformational alterations.

More recently Alben et al. undertook a detailed FT-IR investigation of the dynamic interaction of carbon monoxide with a_3 Fe and Cu_B in cytochrome c oxidase at low temperature [18]. They found that photolyzing the Fe-CO bond results in the transfer of CO to Cu_B . This process is reversible in the absence of light above 140 K. That the a_3 FeCO showed a very narrow ν (CO) peak, while the Cu_B exhibited a much broader one, indicated that the carbon monoxide in a_3 FeCO is in a highly ordered environment separated from the Cu_B atom which is in less ordered, more flexible surroundings.

Mantsch and co-workers have employed FT-IR spectroscopy in the elucidation of the structure and functional properties of biomembranes. They have designed an integrated system, including hardware and software modifications [19,20], to study several aspects of the thermal behaviour of natural phosphatidylethanolamines, phosphatidylcholines and phosphatidylsulfocholines, by monitoring subtle changes in the absorption bands characteristic of specific functional groups.

FT-IR spectroscopy has recently been used to examine metal ion interactions with DNA nucleotides [21], as well as the interactions of certain drugs, such as platinum compounds with anti-tumour activity [e.g., cis-Pt(NH₃)₂Cl₂], with DNA [22].

The monitoring of blood protein interactions with polymers is of great importance for the assessment of the suitability of a material as an implant in the body (e.g., artificial heart valves, indwelling catheters, dialysis membranes and other artificial organs). The event which seems to determine how well the body will tolerate a given implant is protein adsorption, since adsorption of certain proteins can induce thrombosis (clotting). The coupling of FT-IR with ATR (attenuated total reflection) has provided the necessary sensitivity to detect very thin layers of adsorbed proteins on various surfaces [23-25]. Gendreau et al. have

utilized this technique for the first time to study protein adsorption from flowing, intact dog blood on a polymer-coated germanium surface [24] (Figure 5.1). They demonstrated that within the first few seconds of flow rapid adsorption of albumin and glycoproteins took place; immediately thereafter, increased amounts of fibrinogen and other proteins began to adsorb, displacing albumin until finally a clot was formed. This example represents one of the only ex vivo biomedical experiments involving FT-IR spectroscopy.

Clearly the use of FT-IR spectroscopy in the study of biological systems has not been widespread. As biological, biochemical and medical researchers become more aware of the enhanced sensitivity and flexibility of this nondestructive spectroscopic technique, new applications will certainly emerge. In Chapter 6, the investigation of such an application, involving the use of FT-IR spectroscopy to detect organometallic-labelled steroid hormones in their target tissue for purposes of receptor assay, will be described. Further utility of FT-IR in the study of some selected chalcocarbonyl porphyrin derivatives will be presented in Chapter 7.

Chapter 6

FT-IR Spectroscopy in Biological Assay

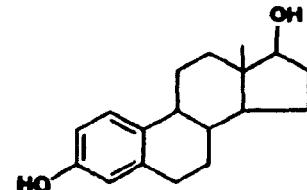

6.1 Introduction

The determination of hormonal receptor concentrations in tissue requires highly sensitive techniques in view of the minute quantities involved (nanograms or less per gram of tissue). Radioassay has been the principal technique used in measuring such low concentrations. Though this method has proved quite powerful and is widely accepted, it has certain drawbacks: high cost of radioisotopes, health hazards, limited variety of usable isotopes, labelling difficulties, chemical and biochemical instability (including radiolysis in solution). These problems have encouraged the search for non-radioisotopic methods in biological assay.

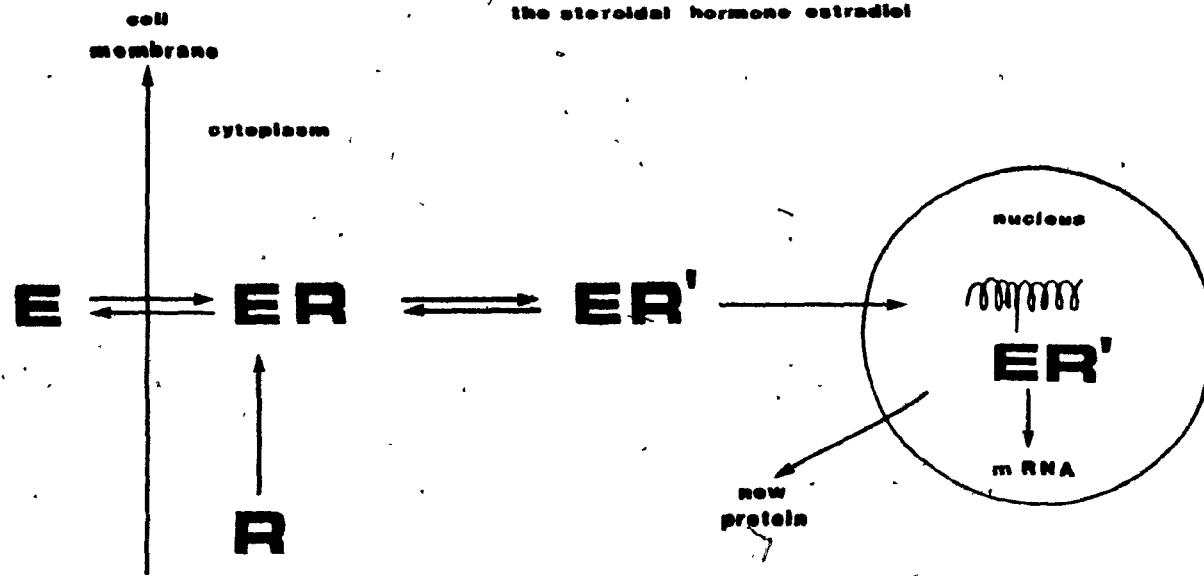

In this chapter, the investigation of the feasibility of a new method of receptor assay will be presented. The method is based on the labelling of a steroid hormone with a metal tricarbonyl moiety and detection of this label in the hormone-receptor complex by FT-IR spectroscopy. The receptor chosen for the investigation was the estrogen receptor. The approach to receptor assay described in this chapter represents one of the few examples reported of research on the incorporation of organometallic labels into

estrogens in order to label the estrogen receptor for diagnostic or therapeutic purposes. Recently estrogen has been labelled with boron-10 atoms (in the form of a cage carborane molecule containing ten boron atoms and two carbon atoms) by Hadd [1] (patent under review), with the hope that such a label would be taken up by cancerous cells that contain estrogen receptors. Subsequent bombardment with a low-energy neutron beam would split the ^{10}B , giving off alpha particles causing necrosis in the immediate area. Cais and co-workers [2] have investigated the determination of metal labels in steroids by atomic absorption spectrometry. Dilution of the metal-labelled steroids in phosphate buffer yielded an atomic absorption calibration curve in the 20-500 ng ml⁻¹ range for Fe-labelled steroid. However, no in vitro or in vivo studies have been performed to date to assess the utility of this method for receptor assay.

The process by which specific estrogen binding to its receptor takes place has been traditionally described as follows: the estrogen enters the target cell from the blood stream and interacts with specific receptor proteins in the cytoplasm, forming a non-covalent, high-affinity complex. This complex then enters the cell nucleus and ultimately effects new protein synthesis [3] (Figure 6.1). However, recent studies utilizing monoclonal antibodies to estrophilin (estrogen receptor protein) [4] and cell enucleation [5]

the steroidal hormone estradiol

- E** = STEROIDAL HORMONE
- R** = RECEPTOR
- R'** = MODIFIED RECEPTOR

Figure 6.1. Traditional representation of the mode of action of a steroidal hormone in a target cell. Adapted from A.L. Lehninger, "Biochemistry", 2nd ed., Worth Publishers, New York, 1975, p. 824.

have provided evidence that the estrogen receptor resides solely in the cell nucleus. It has been postulated that the observed localization of the free receptor in the cytosolic fraction of cell homogenates occurs during homogenization [5].

The interaction of estrogens with their specific receptors has been the focus of considerable research [6] and changes in estrogen receptor levels are implicated in certain hormone-dependent cancers [7]. Estrogen receptor levels have been determined by radiochemical techniques using a variety of radiolabelled modified estrogens (e.g., ^3H , ^{14}C , ^{125}I) [6].

The synthesis of chromium tricarbonyl derivatives of steroids has been reported in the literature [8,9]. $(\text{est})\text{Cr}(\text{CO})_3$ has been prepared by heating $\text{Cr}(\text{CO})_6$ and estradiol in the presence of donor solvents such as THF and $n\text{-Bu}_2\text{O}$. The A ring is the preferred site^b for complexation because it acts as a six-electron donor to complete an 18-electron configuration for the $\text{Cr}(\text{CO})_3$ moiety. Since the $\text{Cr}(\text{CO})_3$ moiety can complex on either side of the A ring, two diasteriomers with the $\text{Cr}(\text{CO})_3$ group either trans (α) or cis (β) to the methyl group at the 13-position of the steroid are obtained. These isomers have recently been separated using thin layer chromatography [10]. The α isomer was found to be more stable as well as being the preferred pro-

duct; this situation was attributed to the greater steric hindrance encountered by the tricarbonyl moiety in the cis product due to the methyl group.

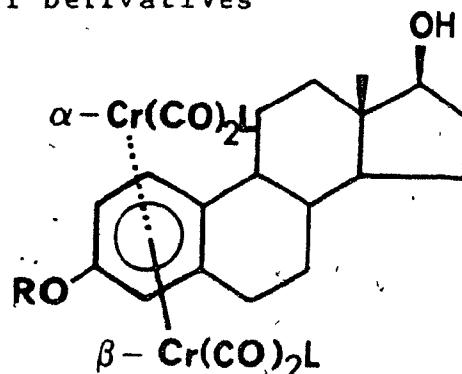

The first requirement that must be met by these derivatized hormones if the organometallic moiety is to serve as a label for receptor assay is that they must be stable in aqueous media. The second requirement is that they must retain a high specificity for their particular receptor. The presence of the hydroxyl group at the 3-position of the steroid was found to contribute to the rapid decomposition of (est)Cr(CO)₃ complexes in solution, yielding estradiol and chromium salts. Incorporation of a protecting group at the 3-hydroxyl group of the estradiol resulted in stabilization of the product, presumably by shielding the metal tricarbonyl moiety from attack by solvent molecules.

Enhancing the stability of the complex in solution invariably decreases receptor binding. Thus a variety of protecting groups were examined [11] in order to select the modified estradiol with the highest affinity for the estrogen receptor. The binding affinities of the modified estradiol complexes were assayed by competitive binding studies using uncomplexed, tritiated estradiol hormone. (A drawback of this procedure is the inability to measure accurately the levels of high-affinity, non-specific binding of the modified estrogen complexes.) Both the α and β complexes with a

variety of protecting groups at the 3-hydroxyl group were tested and the relative binding affinities (RBA) were calculated (Table 6.1). When the hydroxyl group is maintained away from the steroid skeleton by a spacer chain ($\text{H}-\text{O}-(\text{CH}_2)_3-\underline{9}$) the highest affinity was observed. It appears also that the fixation site of the tripod on the A ring of the steroid strongly discriminates the α and β diasteriomers with respect to their receptor recognition properties. While the β -isomers (6,11) show relatively modest affinities, the α -isomers (5,7,10) bind with significantly higher affinities. Among the complexes listed in Table 6.1, compound 10 has the highest RBA value, 28, which is very close to that of the free ligand 9 (RBA = 37), and thus may serve as an excellent choice on the basis of the recognition criteria.

In this chapter, an investigation of the utility of FT-IR spectroscopy in the detection of the modified, organometallic-labelled estrogens at physiological concentrations will be presented and the potential and limitations of the use of FT-IR in their quantitative analysis as an alternate technique to radioassay will be discussed.

Table 6.1. Relative Binding Affinities of Modified Estradiols
and Their Chromium Chalcocarbonyl Derivatives^a

Compound	R/metal chalcocarbonyl moiety	Relative binding affinity (RBA) ^b
<u>1</u>	H/-	100
<u>4</u>	Si(Me) ₂ (t-Bu)/-	11
<u>5</u>	Si(Me) ₂ (t-Bu)/ α -Cr(CO) ₃	1.05
<u>6</u>	Si(Me) ₂ (t-Bu)/ β -Cr(CO) ₃	0.36
<u>7</u>	Si(Me) ₂ (t-Bu)/ α -Cr(CO) ₂ (CS)	1.5
<u>9</u>	HO(CH ₂) ₃ /-	37
<u>10</u>	HO(CH ₂) ₃ / α -Cr(CO) ₃	28
<u>11</u>	HO(CH ₂) ₃ / β -Cr(CO) ₃	1.75

^aData from References 10 and 11.

^bThe relative binding affinity represents the ratio of the concentration of unlabelled estradiol to that of the compound required to inhibit half of the binding of [³H]-estradiol in a competitive binding assay, with the RBA of estradiol set at 100%.

6.2 Experimental

The general procedure for organometallic labelling of the steroid has been published previously [9] and is not included here. However, the biochemical assay has not been fully published. It should be noted that the procedures described in Sections 6.2.1 and 6.2.2 were performed by A. Vessières and are only included here to provide the reader with the necessary background in the sample preparation required for the FT-IR studies.

6.2.1 Sheep Uterus Estrogen-Receptor Purification

Young sheep uteruses were obtained from the slaughterhouse and were put in ice immediately after their removal from the animal (the weight of the uterus should not exceed 10 g). All further manipulations were performed between 0 and 4°C. Surrounding fat was first removed from the uteruses, which were then washed with 0.9% NaCl solution and weighed. They were then homogenized in a "Waring Blender" in twice their volume of Tris-Saccharose (Tris pH 7.5, 50 mM; Saccharose, 0.25 M, mercaptoethanol, 1%), and centrifuged for 15 min at 800 x g. After centrifugation the supernatant was filtered through nylon gauze and centrifuged at 105,000 x g for 1 h. The supernatant from this centrifugation constitutes what is called the cytosol. The receptor concentration in the cytosol was measured for one aliquot

using the method described by Thieulant et al. [12]. The cytosol was subsequently divided into small fractions not larger than 10 ml which were kept at -70°C. Periodic measurements of the receptor concentration in these samples showed that under these conditions the level of estradiol receptor remains constant for several months. The amount of cytosol proteins was determined by the Lowry assay using BSA (bovine serum albumin) as a standard. The concentration of proteins in the above preparations was usually 10-12 mg/ml cytosol.

6.2.2 Preparation of Samples for FT-IR Studies

Varying volumes of cytosol were incubated for 4 h at 0°C with known concentrations of the organometallic-labelled estradiol derivatives to yield a final concentration of the label in the range 10^{-8} - 10^{-6} M. At the end of the incubation period, an equal volume of protamine sulfate solution (6 mg/ml) was added to precipitate the proteins. The precipitate obtained was collected by centrifugation (3300 x g, 15 min). After elimination of the supernatant, the precipitate was washed 4 times with 5 ml of phosphate buffer (0.05 M, pH 7.4), twice with 5 ml of distilled water and lyophilized. This provides a white powder which can be used without further treatment for the IR studies. The receptor concentration in these samples was established by competitive

binding assay using ^3H -estradiol to be in the range of 300 fmol per mg of precipitated protein.

6.2.3 Infrared Studies

All solvents used were of spectrograde purity or were distilled under nitrogen prior to use. KBr and CsI (gold label 99.999%) were obtained from Aldrich Chemical Co. Solid samples were pressed into 3- or 5-mm pellets, using a "Qwik Handi-Press Set" available from Aldrich. Samples mixed with KBr or CsI were ground in stainless steel vials using "Wig-L-Bug", also available from Aldrich.

All spectra were recorded with a Nicolet 6000 Fourier transform-infrared spectrometer equipped with a mercury cadmium telluride (MCT) detector (Infrared Associates, New Brunswick, NJ), and having a beam diameter at the focal point of 5 mm. The pellet holder was supported on an X-Y translator, so that the sample position could be adjusted to obtain maximal detector response. Ten thousand to thirty thousand scans (with a medium correlation) were accumulated and co-added using the LWA program listed in Appendix C. The mirror velocity was adjusted empirically to 0.640 cm s^{-1} for optimum detector sensitivity; the gain was increased to allow the interferogram to reach 50-75% of its height in a background scan recorded for the empty pellet holder with a source aperture of 6.3 mm. The relative gain of all the

points after the first 1024 set was increased by a factor of eight. The co-added interferograms were apodized using the Happ-Genzel function and Fourier transformed with one level of zero filling to yield a resolution of 4 cm^{-1} .

6.3 Results and Discussion

The preliminary results presented below were obtained with an organometallic-labelled estradiol derivatized at position 3 with a silyl group (compound 5, Table 6.1). The results of further studies with compound 10, having the highest RBA of any derivatized steroid complex tested, will be shown later in this section.

In the receptor assay procedure under investigation, the organometallic-labelled hormone is incubated with the cytosol containing the hormonal receptor, forming an organometallic-labelled receptor complex (OLRC), and the cytosol proteins are then precipitated by addition of protamine sulfate. The precipitate is then lyophilized, yielding a white powder. The same procedure is followed in the absence of the organometallic-labelled hormone to yield the apoproteins. Figure 6.2 shows the spectrum of the apoprotein, diluted in a CsI matrix. Of particular interest here is the lack of absorption in the region between 2200 and 1800 cm^{-1} , thereby limiting any interference from the protein backbone.

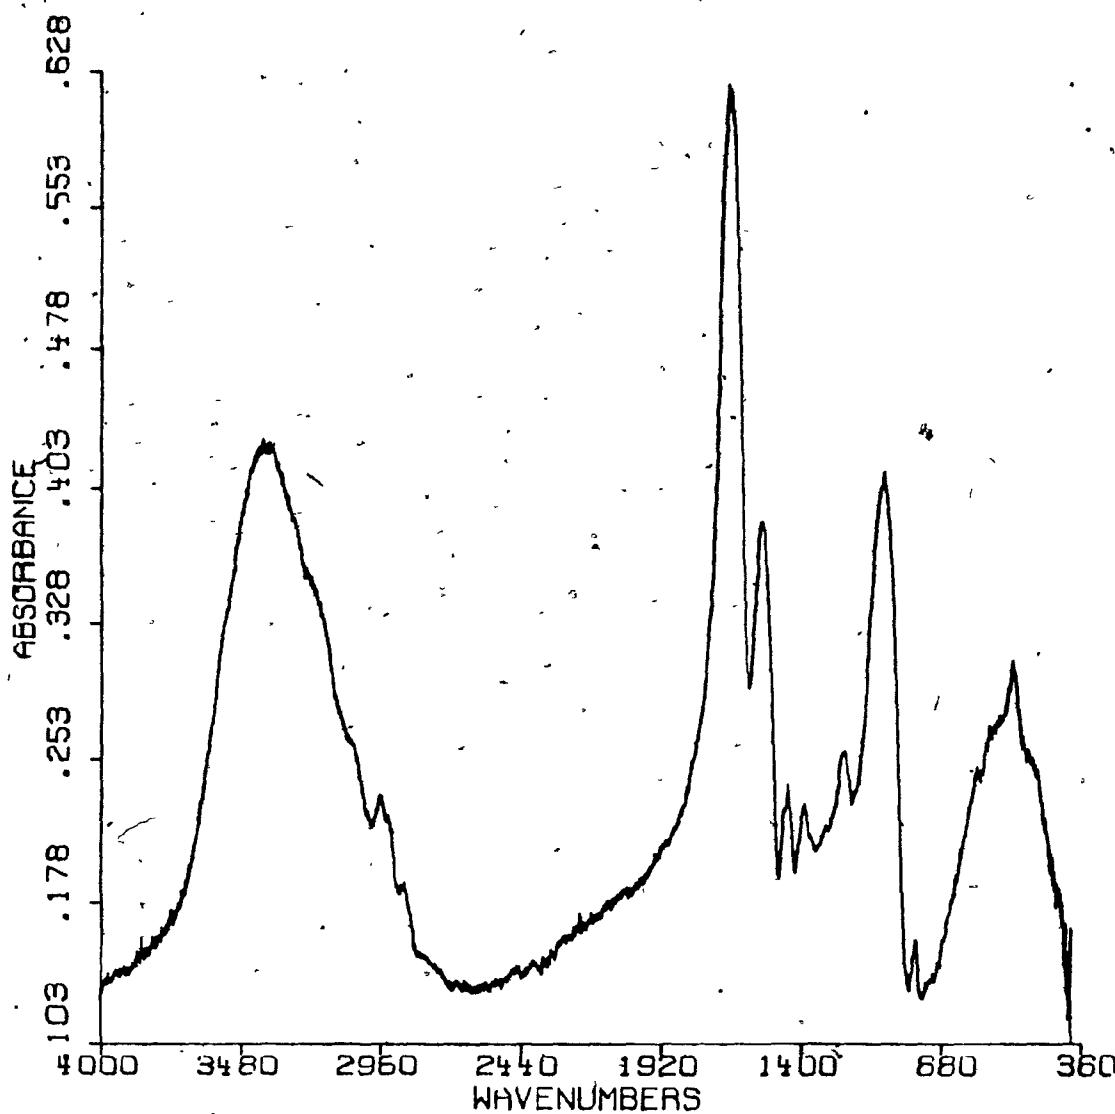

Figure 6.2. FT-IR spectrum of the proteins precipitated by protamine sulfate from the cytosol of sheep uterus (CsI pellet; 32 scans; 4 cm⁻¹ resolution).

in the detection of the metal carbonyl stretching vibrations which occur in this region. Samples in which the proteins from the cytosol had been precipitated with hydroxyapatite rather than protamine sulfate were also examined. The choice of this precipitating agent proved unsuitable for the purposes of this work since the FT-IR spectra of these samples exhibited four weak peaks in the 2200-1800 cm^{-1} region, presumably due to overtones of hydroxyapatite P-O stretching modes.

The spectrum of $\text{Cr}(\text{CO})_3$ -labelled modified estradiol (compound 5) is presented in Figure 6.3. The much larger relative intensity of the metal carbonyl vibrations of the $\text{Cr}(\text{CO})_3$ moiety at 1956(a₁) and 1876(e) cm^{-1} compared to the estradiol backbone vibrations clearly indicates the advantage of the $\text{Cr}(\text{CO})_3$ label in the detection of low concentrations of steroids by FT-IR spectroscopy.

Since the ratio of receptor to total precipitated proteins is very small, and since mixing with CsI or KBr or dissolution would dilute the sample, thus weakening the IR intensity of the carbonyl peaks, the protein was pressed into a 3-mm diameter minipellet without addition of CsI. The choice of the 3-mm diameter, which is less than the diameter of the IR beam (5 mm), represents a compromise between allowing the maximum amount of energy to pass through the sample and minimizing the amount of protein required.

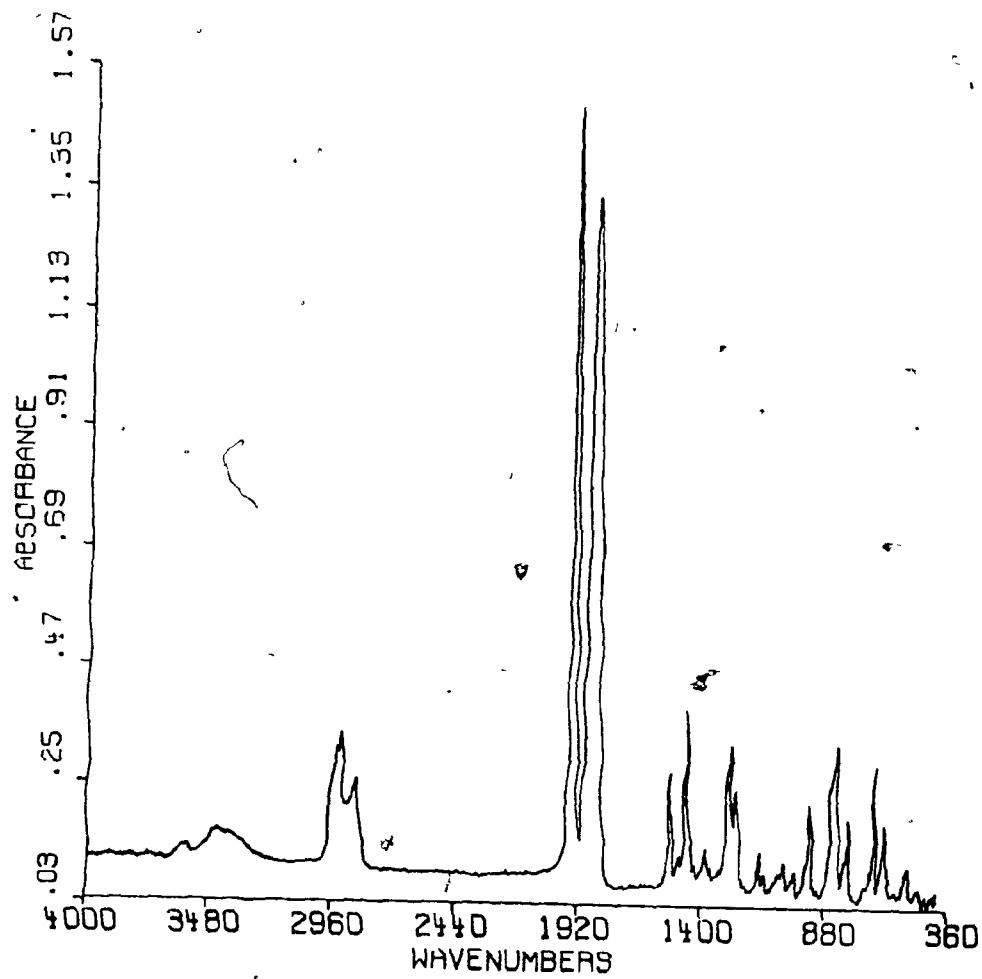

Figure 6.3. FT-IR spectrum of (RO-est)Cr(CO)₃ (compound 5) in CsI.

The spectrum of a pressed pellet of the precipitated proteins containing the OLRC (Figure 6.4) demonstrates the importance of the "window" in the carbonyl region since all the absorptions of the steroid skeleton are masked by the enormous absorptions due to the precipitated proteins. The carbonyl region of this spectrum is shown in Figure 6.5; two peaks at 1955(a_1) and 1881(e) cm^{-1} are observed which correspond well to the $\nu(\text{CO})$ modes identified in the spectrum of compound 5 in a CsI matrix.

The spectrum in Figure 6.5 was obtained by co-adding 20,000 scans. Co-adding spectra results in an increase in the S/N ratio equivalent to (number of scans) $^{1/2}$. This can be a time-consuming process; however, if the number of data points collected is reduced (i.e., lower resolution), the time required to obtain a given spectrum is shortened by (lower res./higher res.) 2 . Accordingly, enhancing the S/N ratio is achieved much faster at lower than at higher resolution. Since the width at half-height of the carbonyl peaks is approximately 17 and 25 cm^{-1} for the a_1 and e modes, respectively, 4 cm^{-1} resolution is quite acceptable as no further information could be gained from scanning at higher resolution [13].

In order to confirm that the peaks observed in the carbonyl region can be attributed to the carbonyl stretching vibrations of the $\text{Cr}(\text{CO})_3$ moiety, samples of the precipita-

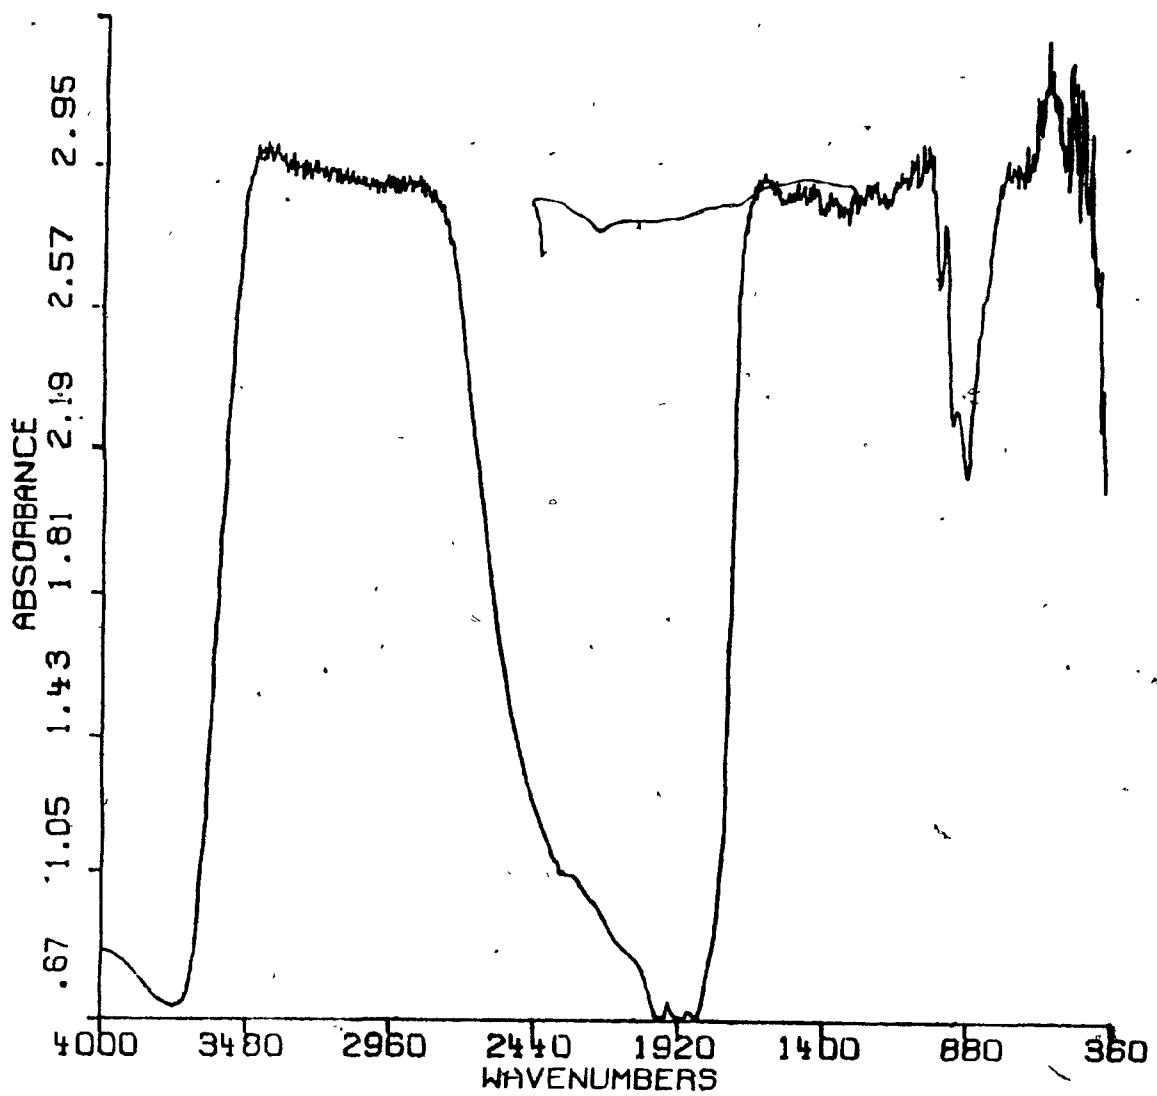

Figure 6.4. FT-IR spectrum of a pressed pellet of the proteins precipitated from the cytosol of sheep uterus after incubation with (RO-est)Cr(CO)₃ (compound 5) (3-mm mini-pellet; 20,000 scans; 4 cm⁻¹ resolution).

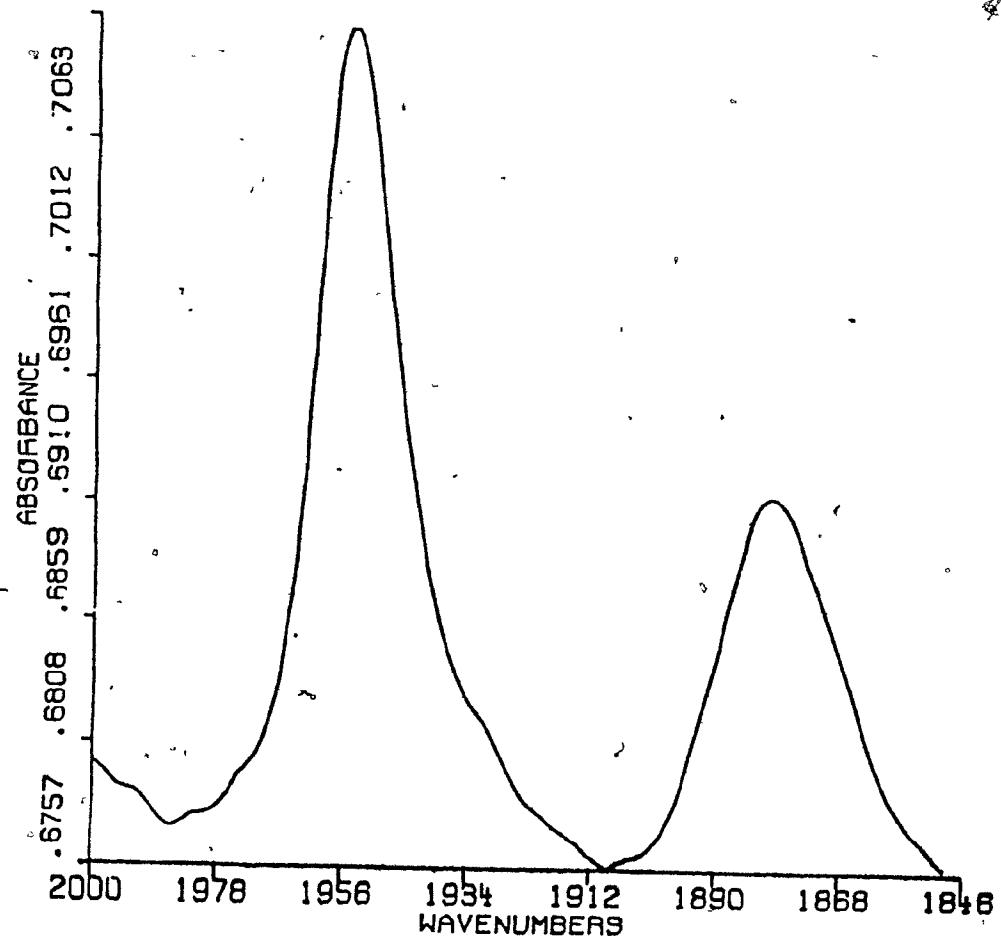

Figure 6.5. Expansion of the $\nu(\text{CO})$ region of the FT-IR spectrum in Figure 6.4.

ted proteins obtained after incubation of the thiocarbonyl analogue of $(RO\text{-est})\text{Cr}(\text{CO})_3$ (compound 7) [10] in the presence of the receptor under the same conditions as described for the tricarbonyl analogue were obtained. The FT-IR spectrum of compound 7 in CsI is shown in Figure 6.6. The $\nu(\text{CS})$ vibration is observed at 1204 cm^{-1} and the $\nu(\text{CO})$ modes at 1954 and 1895 cm^{-1} . The carbonyl region of the FT-IR spectrum of the protein sample (Figure 6.7) shows two $\nu(\text{CO})$ bands which are shifted as expected in going from the tricarbonyl to the thiocarbonyl analogue. This observation provides confirmation that the bands seen are indeed due to the carbonyl absorptions. The thiocarbonyl stretching vibration (1200 cm^{-1}) is buried beneath the extremely intense vibrational modes of the proteins.

In order to assess the potential of this method in quantitative determination, investigation of the intensity of the carbonyl peaks of the $\text{Cr}(\text{CO})_3$ label as a function of pellet weight (i.e., amount of protein) was undertaken. Clearly a linear relationship is required if the FT-IR measurements are to serve as a basis for receptor assay.

Various methods of treating the data were investigated using CsI pellets of varying weights with the same concentration of $(RO\text{-est})\text{Cr}(\text{CO})_3$ (compound 5) so as to ascertain the best approach to the correlation of carbonyl intensity with amount of complex present (as represented by wt. of the

sample). Table 6.2 lists the four methods examined. These include peak height, peak area, and first derivative and second derivative techniques. In all cases, data were analyzed for the a_1 $\nu(CO)$ mode rather than the broader e mode. The results show that the integrated band area method provides the best correlation between band intensity and the concentration of the organometallic complex by virtue of having the highest correlation coefficient and the largest slope. The peak height measurements are also seen to correlate well with concentration, while the derivatives are somewhat less reliable. Differentiation enhances narrow spectral lines, and this enhancement can be used advantageously in the analysis for trace quantities of small or highly symmetrical molecules. Conversely, the broader the band the less useful this feature becomes [14]. The second derivative spectrum of the $(RO\text{-}est)Cr(CO)_3$ complex is presented in Figure 6.8. The second derivative of the a_1 mode can be clearly seen while that of the broader e mode is poorly defined.

Subsequent to these studies of compound 5 in CsI, FT-IR spectra were recorded for a series of pellets of varying weights prepared from the precipitated proteins containing the OLRC without addition of CsI. The areas under the a_1 $\nu(CO)$ mode in these spectra were plotted as a function of pellet weight (Figure 6.9). The linearity of this plot is

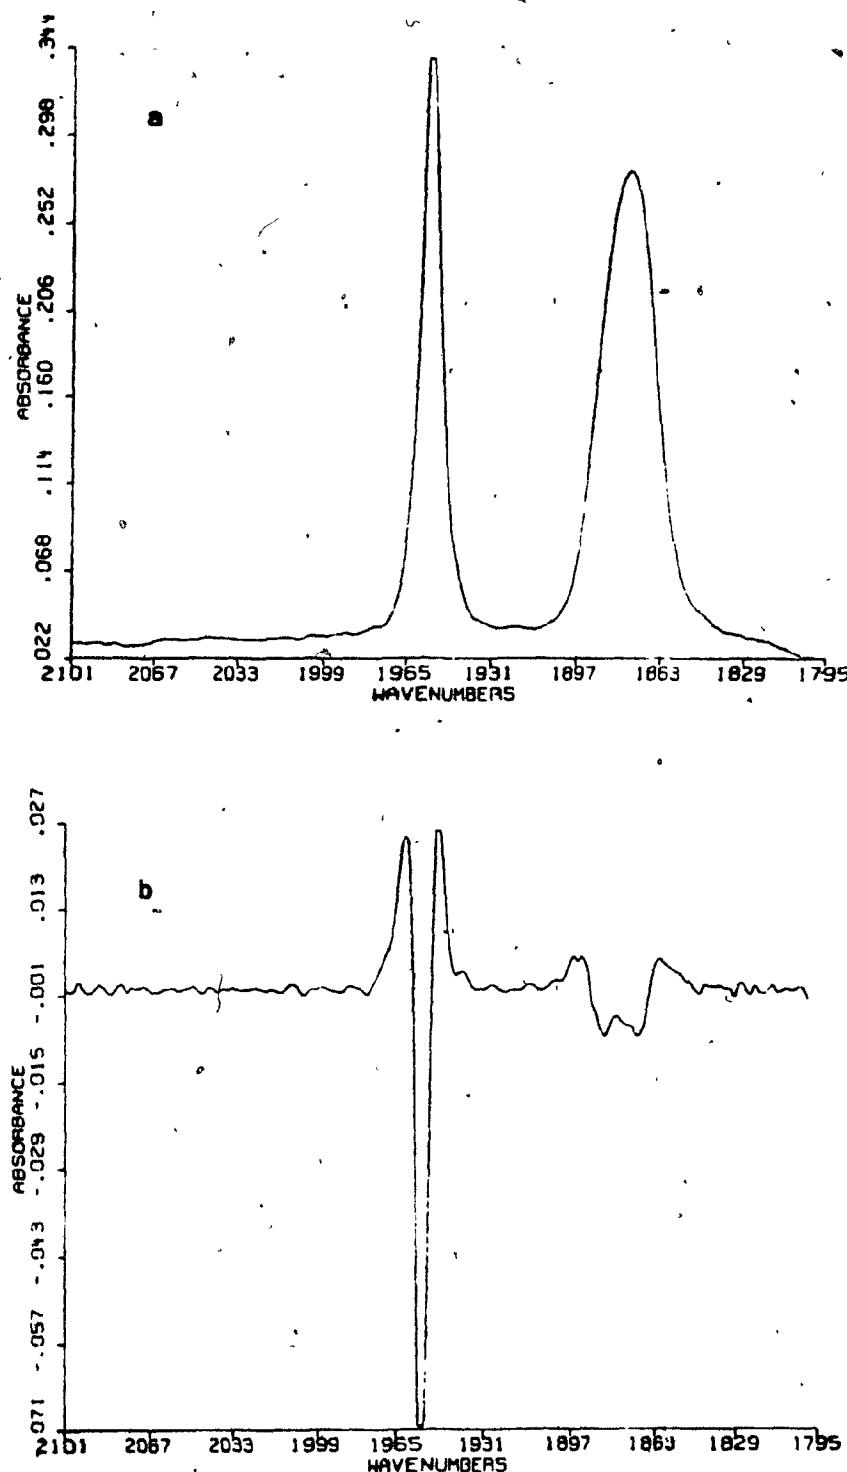

Figure 6.8. The $\nu(\text{CO})$ region in the FT-IR spectrum of compound 5 in ethyl acetate (a) and the second derivative of this spectrum (b).

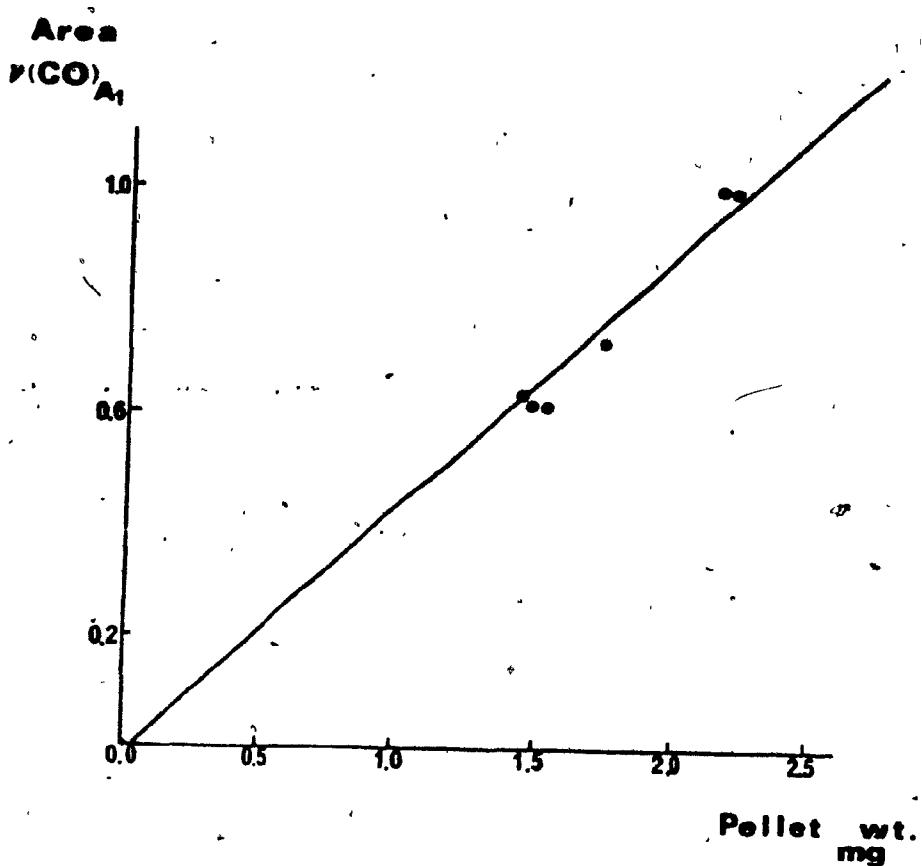

Figure 6.9. Plot of the area under the $\nu(\text{CO})$ mode of the (R0-est) $\text{Cr}(\text{CO})_3$ label (compound 5) in the FT-IR spectra of pressed pellets (3-mm diameter) of a protein sample vs. pellet weight.

satisfactory in the range of pellet weights from 1.4 to 2.5 mg ($r = 0.98$). Samples weighing less than 1.4 mg represent insufficient material to form a pellet. For pellet weights greater than 2.5 mg, significant deviations from linearity occurred, indicating self-absorption or a decrease in energy throughput in these thicker pellets. Therefore, although it would be advantageous to use pellets of the maximum thickness possible in order to enhance the intensity of the peaks due to the $\text{Cr}(\text{CO})_3$ label, pellet weights under 2.5 mg must be employed for quantitative accuracy.

In order to obtain an approximate value for the amount of $\text{Cr}(\text{CO})_3$ label in these pellets, the integrated absorptivity of the a_1 mode of $(\text{RO-est})\text{Cr}(\text{CO})_3$ (compound 5) in CsI was calculated from the area under the $a_1 \nu(\text{CO})$ mode (A_{int}) as a function of pellet weight according to the following derivation:

$$A_{int} = \int A_v dv$$

$$= bc \int \epsilon_v dv$$

where $\int \epsilon_v dv$ is the integrated absorptivity = ϵ_{int}

b = thickness of the pellet

c = wt. of $(\text{RO-est})\text{Cr}(\text{CO})_3 / \pi r^2 b$, for a pellet of diameter $2r$ and thickness b

This holds true if $r_{beam} > r_{pellet}$; also if $r_{pellet} = r_{beam}$, maximum throughput is achieved with minimum sample weight.

The wt. of $(RO\text{-est})Cr(CO)_3$ in the pellet, w_{com} , is given by:

$$w_{com} = C_{com} \times (\text{wt. pellet})$$

where C_{com} is the known concentration by weight of the complex in the CsI matrix and wt. pellet \approx wt. CsI in pellet.

Thus

$$A_{int} = \epsilon_{int} \times b \times (w_{com}/\pi r^2 b)$$

$$= \epsilon_{int}/\pi r^2 \times C_{com} \times (\text{wt. pellet})$$

Plotting A_{int} vs. (wt. pellet) gives a slope $= \epsilon_{int}/\pi r^2 \times C_{com}$.

The measurement of A_{int} (area under the $a_1 v(CO)$ mode integrated from 1984.0 to 1924.0 cm^{-1}) for various weights (mg) of pellets of $(RO\text{-est})Cr(CO)_3$ in CsI having a concentration

$$C_{com} = 5.54 \times 10^{-4} \text{ g } (RO\text{-est})Cr(CO)_3/\text{g CsI}$$

gave a slope, through least-squares analysis, of 0.541 ($r = 0.9999$). Thus

$$\epsilon_{int} = \frac{0.541 \text{ mg}^{-1} \times \pi \times (0.15)^2 \text{ cm}^2}{5.54 \times 10^{-7} \text{ g } (RO\text{-est})Cr(CO)_3/\text{mg CsI}}$$

$$= 6.88 \times 10^4 \text{ cm}^2 \text{ g}^{-1}$$

Using this value, the integrated absorbance expected for the $\alpha_1 \nu(\text{CO})$ mode of compound 5 (mol. wt. = 521.47) labelling all the receptor sites in a 2-mg pellet containing 300 fmol mg⁻¹ of receptor protein can be estimated as:

$$\begin{aligned} A_{\text{int}} &= [6.88 \times 10^4 / \pi(0.15)^2] \times (300 \times 10^{-15})(521.47) \times 2 \\ &= 3.04 \times 10^{-4} \end{aligned}$$

This estimated integrated absorbance value is significantly lower than that observed for the precipitated proteins labelled with compound 5 (Figure 6.9). This indicates a large degree of high-affinity, non-specific binding in these samples which may be attributed to the initial incubation of the receptor with a high concentration of compound 5 (10^{-6} M) and possibly insufficient washing of the precipitated proteins [11].

Further studies were carried out with compound 12 ([$^{17}\alpha$ -³H]compound 10). The elegant synthesis by Jaouen et al. [15] of this doubly labelled complex is illustrated in Figure 6.10. It should be noted that introduction of the ³H label at a carbon too close to the metal resulted in autoradiolysis of the organometallic moiety. FT-IR studies of

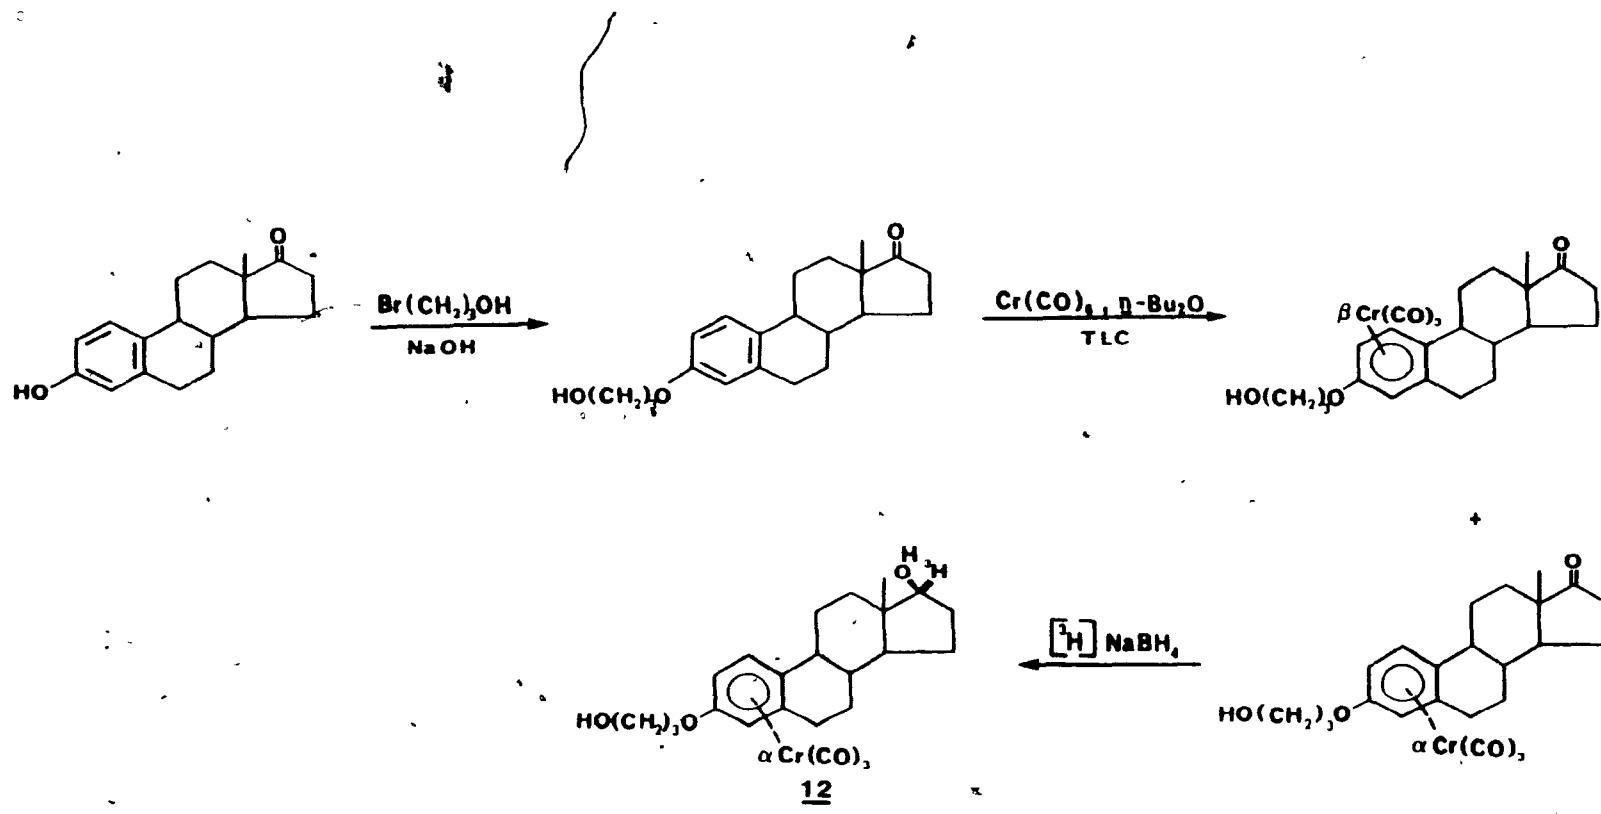

Figure 6.10. Synthesis of compound 12, a tritiated, $\text{Cr}(\text{CO})_3$ -labelled modified estradiol, as described in Reference 15.

compound 12 indicate that it is quite stable in solution.

Figure 6.11a shows the $\nu(\text{CO})$ region of the FT-IR spectrum of a sample obtained by in vitro incubation of compound 12 with sheep uterine cytosol at approximately the same concentration ($\approx 10^{-8}$ M) as currently used in radiochemical assays with estradiol itself. The carbonyl intensities in this spectrum are clearly much lower than those observed with compound 5. Although the S/N ratio is high enough to discern definitively the presence of the carbonyl vibrations, the areas of these peaks cannot be measured with quantitative accuracy. The results of a competitive binding assay with free diethylstilbestrol (DES) show that compound 12 is bound specifically and reversibly to the uterine estrogen receptor [15] (Table 6.3). It should be noted that in this sample the level of non-specific binding is significantly lower than that of specific binding, indicating the high degree of specificity of compound 12 for the estrogen receptor. Therefore, the weak carbonyl peaks detected in Figure 6.11a are due in large part to the OLRC.

The reversibility of the binding between compound 12 and the receptor was demonstrated by FT-IR, as well as by radioassay. The spectrum of a sample obtained subsequent to the competitive binding experiment with excess DES was recorded. The carbonyl region of this spectrum (Figure 6.11b) reveals the absence of any peaks due to the OLRC,

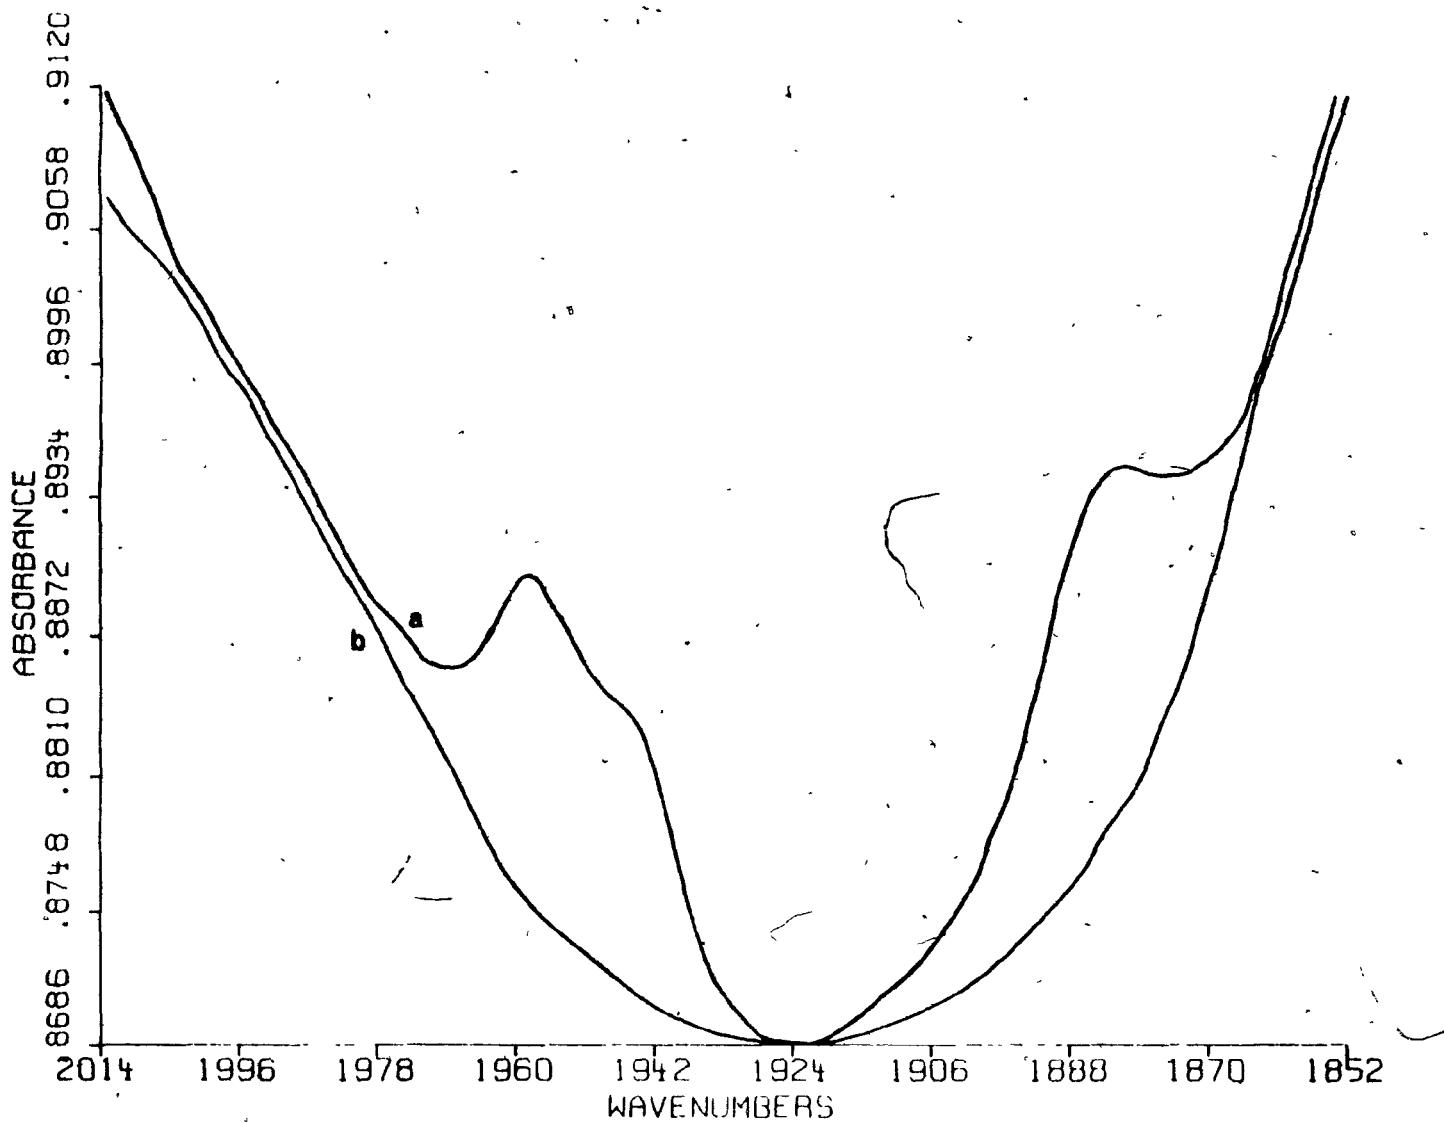

Figure 6.11. FT-IR spectrum (26,000 scans, 4 cm^{-1} resolution) in the $\nu(\text{CO})$ region of proteins precipitated from the cytosol of sheep uterus after incubation with (a) compound 12 and (b) compound 12 and a 100-fold excess of diethylstilbestrol in a competitive binding assay.

Table 6.3. Determination of Specific and Non-specific Binding of Compound 12 and Estradiol in Sheep Uterine Cytosol by Radioassay^a

Ligand	Added	Radioactivity (dpm ml ⁻¹)		
		Bound without DES	Bound with DES	Specifically bound

[6,7- ³ H]- 17 β -estradiol	535,466	166,333	23,080	143,253 (28%)

^aResults from Reference 15. Portions (500 μ l) of sheep uterine cytosol were incubated at 0°C for 6 h with either [6,7-³H]17 β -estradiol (4.7 nM; specific activity, 52 Ci mmol⁻¹) or compound 12 (6.3 nM; specific activity, 3.3 Ci mmol⁻¹). Non-specific binding was determined by using a 100-fold excess of unlabelled diethylstilbestrol (DES). Bound fractions were determined by protamine sulfate precipitation.

because of the binding of DES to the receptor, and also demonstrates the relative insensitivity of the FT-IR measurements at the present time in that the non-specific binding of compound 12 measured by the radioassay was not detected in the FT-IR spectrum.

The measurement of non-specific binding can also be accomplished by deactivating the receptor (usually by heating) and then incubating the denatured receptor with the hormone. The FT-IR spectrum of a sample prepared by thermal deactivation of the receptor protein and subsequent incubation with the organometallic-labelled hormone displayed a carbonyl intensity larger than that of the unheated sample. This situation, however, was also observed radioisotopically [11], indicating that denaturation contributes in these samples to increasing the non-specific binding.

The FT-IR spectra of the organometallic-labelled receptor complex may also be used to elicit some information on the polarity of the receptor binding site. The dependence of $\nu(\text{CO})$ frequencies of metal carbonyl complexes on solvent polarity is well established [16]. Table 6.4 shows the shift of the carbonyl peaks of compound 10 to lower frequency as the polarity of the solvent increases. Comparison of these data with the positions of the $\nu(\text{CO})$ modes in the protein samples suggests that the carbonyl moiety in the OLRC lies in a polar environment. However,

Table 6.4. $\nu(\text{CO})$ -Frequencies (cm^{-1}) of (R₀-est)Cr(CO)₃ (Compound 10) in Solvents of Varying Dielectric Constant (ϵ)

^as = soluble; ss = slightly soluble; vs = very soluble.

this does not provide definitive evidence of a polar environment at the receptor binding site since the carbonyl moiety may not be in proximity to the actual binding site. Also, the proteins were precipitated using protamine sulfate which could be a contributing factor to the polarity of the environment. Recent studies have shown that the addition of hydrophobic substituents such as aliphatic chains in the 7α -position of estradiol increases the affinity of the steroid for the receptor binding site [17]. This could be considered as evidence for hydrophobic character of the binding site. However, further studies [17] have shown that addition of aliphatic chains of varying length in the 6α -position brings about a significant decrease in the binding affinity of the steroid, thereby demonstrating the variability in the polarity of the receptor binding site.

The FT-IR measurements reported here have shown that FT-IR spectroscopy can provide qualitative information on hormone-receptor binding and has the potential to serve as a technique for quantitative determination of receptor concentration. However, the very weak intensities of the carbonyl peaks in Figure 6.11a, obtained from a sample in which there is a higher level of specific binding than of non-specific binding, indicate that receptor assay by FT-IR spectroscopy is not as yet feasible. The transformation of this technique from the qualitative to the quantitative realm will

require enhanced sensitivity of the FT-IR spectrometer in the carbonyl region of the spectrum. Possible instrumental modifications that may achieve such enhancement include the use of more sensitive detectors and larger collection mirrors after the sample. The FT-IR spectrometer can be interfaced with a variety of specialized detectors. Room temperature (triglyceride sulfate, TGS) detectors are not suited for fast-scanning spectrometers working in the mid-IR region because of their slow response time. Mercury cadmium telluride (MCT) detectors give a much faster response time and are well suited for the mid-IR region, the faster response time significantly decreasing data acquisition times. The MCT detectors are made of an alloy of HgTe and CdTe, and their spectral response is a function of both specific alloy composition and operating temperature. These detectors operate in the $5000-750\text{ cm}^{-1}$ (MCT A), $5000-400\text{ cm}^{-1}$ (MCT B) and $5000-300\text{ cm}^{-1}$ (MCT C) regions with a typical operating temperature range of 77-295 K. The detector used for obtaining the protein spectra in this study was the MCT B detector operating at 77K. Figure 6.12 illustrates the relative sensitivity of the different detectors commercially available over the mid-IR range. It can be seen that the InSb detector has its maximum sensitivity in the metal carbonyl region ($2200-1850\text{ cm}^{-1}$) and is about an order of magnitude more sensitive in this region than the MCT A.

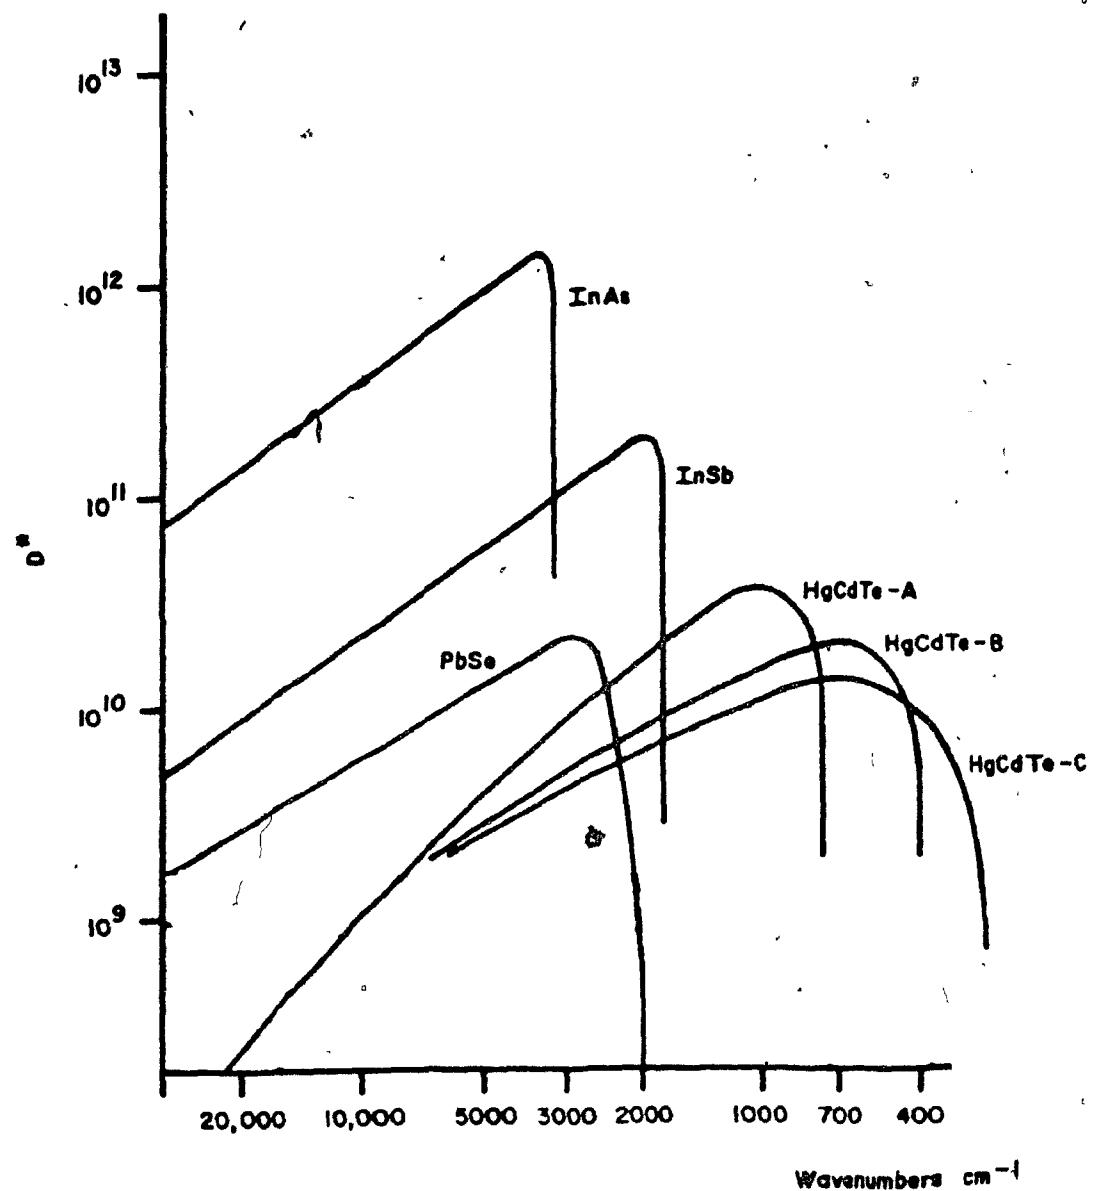

Figure 6.12. Detectors utilized in FT-IR spectrometers and their sensitivity as a function of energy. Adapted from FT-IR documentation supplied by Nicolet Instruments Corporation, Madison, Wisconsin, U.S.A.

detector and approximately forty times more sensitive than the MCT B detector used in this study. Clearly the InSb detector is the detector of choice for further research on the use of metal carbonyl labels in receptor assay. Other recommendations include directly placing the pellet onto the detector, which would reduce energy loss due to scattering. Alternatively, scattered energy could be captured and refocused by using a larger collection mirror to intercept a wider cone of diffusely scattered radiation [18].

6.4 Concluding Remarks

In the present work, it has been shown that FT-IR spectroscopy can detect very low concentrations of metal carbonyl-labelled modified estradiol in protein samples extracted from biological tissue. FT-IR spectroscopy can also in principle be used to calculate the concentration of estradiol-receptor complex in such samples providing that the extinction coefficient for the metal carbonyl peaks in the OLRC can be determined. Thus the combined efforts of judiciously labelling a hormone with an organometallic moiety and subsequent detection of the label by FT-IR spectroscopy yield a novel method for receptor assay which is both non-destructive and possesses none of the drawbacks of radiobisotopic techniques. However, the development of this

technique is in its early stages. In order for it to become viable in clinical use, a minimum of two orders of magnitude increase in the sensitivity of the FT-IR measurements must be achieved. Current work in this area is also being focused on the synthesis of hormone-labelled metal carbonyl cluster complexes [11], which should yield higher integrated $\nu(\text{CO})$ absorptivities.

Chapter 7

Investigation of Chalcocarbonyl(5,10,15,20-tetraphenylporphinato)iron(II) Derivatives by FT-IR Spectroscopy

7.1 Introduction

Many metal-porphyrin derivatives have been synthesized as model compounds for the study of the binding of oxygen and other small diatomic molecules to hemoglobin and myoglobin, as well as to further the understanding of the detoxification mechanisms of porphyrin-containing cytochrome P-450 [1]. Among these porphyrin derivatives, (5,10,15,20-tetraphenylporphinato)iron(II) (FeTPP)[#] is often used because of its stability and convenient synthesis [2,3]. The structure of FeTPP is shown in Figure 7.1. Four nitrogens bind the iron in the equatorial plane through σ -donation, and two ligands can be introduced at the axial positions to complete a pseudo-octahedral structure. The bonding between the iron and the porphyrin also involves π -donation from the filled metal $d\pi$ orbitals to the vacant π^* orbitals delocalized over the porphyrin ring. The extent of the π -back-bonding component of the metal-porphyrin interaction varies with the π -accepting properties of the axial ligands. FeTPP

[#]Unless otherwise stated, FeTPP in the various complexes discussed in this section will represent low-spin Fe(II).

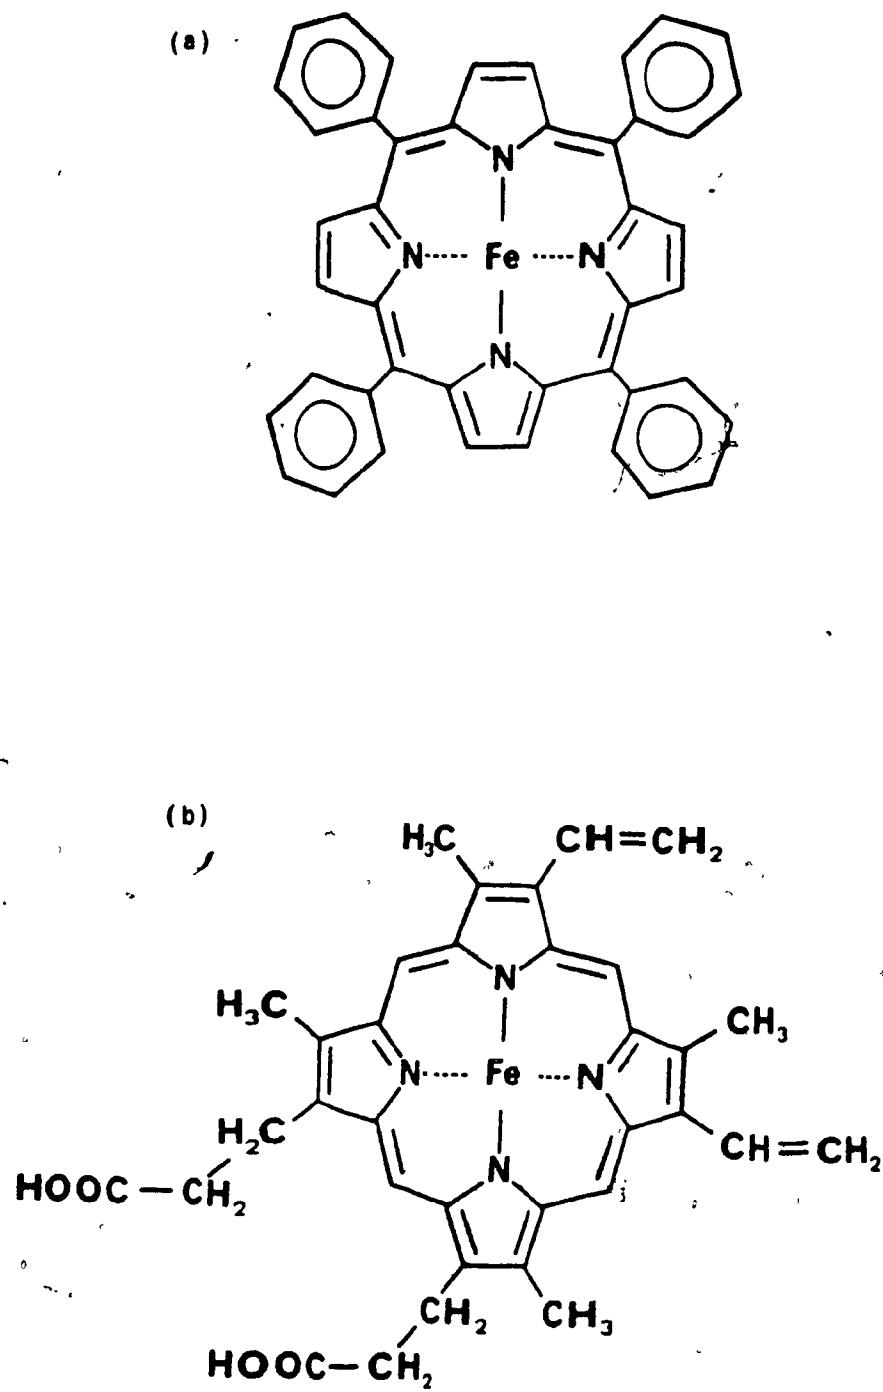

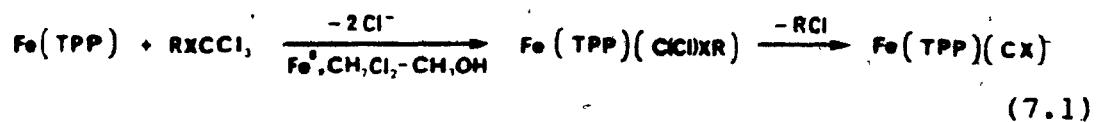

Figure 7.1. Structure of (a) iron tetraphenylporphyrin and (b) protoporphyrin IX.

differs from the naturally occurring protoporphyrin IX found in hemoglobin or myoglobin in that four phenyl groups are introduced at the meso carbons and hydrogens at the β carbons, while in hemoglobin the meso carbons are hydrogen substituted and the β positions have propionic acid, ethylenic or methyl group substituents (Figure 7.1).

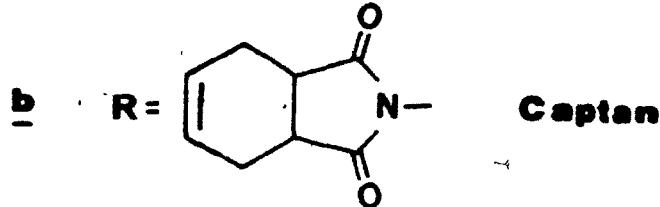

Complexes of the form FeTPP(CO)L with axially bound CO, trans to various ligands L (e.g., py, EtOH, Im, MeIm) are well-known synthetic models for the study of the binding of CO to hemoglobin [4]. Recently, a series of analogous complexes in which the CO ligand is replaced by a thiocarbonyl or selenocarbonyl ligand have been prepared [5-7]. In addition, the pentacoordinated species FeTPP(CX) (X = S, Se) have been obtained [6,7]. Although other metalloporphyrin complexes containing a CS ligand have been synthesized [8], FeTPP(CSe) and Fe(TPP)(CSe)L (L = py, EtOH, MeIm) represent the only examples of the incorporation of a CSe group into a metalloporphyrin system. The bonding properties of both the CS and CSe ligands have been reviewed elsewhere [9] and the stronger σ -donor and π -acceptor capabilities of CS and CSe relative to CO, giving rise to a stronger bonding to low-oxidation state metals, have been emphasized in this thesis. The CS and CSe ligands may also act as π -donors [10] and a greater flexibility in the bonding properties of these ligands relative to those of CO has been demonstrated [11].

The effect of these differences between the CS and CSe ligands, on the one hand, and CO, on the other, in the porphyrin complexes studied here is manifested by the stability of FeTPP(CX) (X = S, Se) whereas the corresponding FeTPP(CO) derivative is only stable under partial CO pressure [12]. The thio- and selenocarbonyl complexes can be heated up to 150°C under vacuum without decomposition [6]. The strength of the Fe-C(X) (X = S, Se) bond is dramatically demonstrated by the stability of the thiocarbonyl and selenocarbonyl complexes towards oxidation in aerated benzene - the half-life of FeTPP(CO)(py) is ~5 min [5] while the corresponding selenocarbonyl complex is stable for hours [7], and FeTPP(CS)(py) or FeTPP(CS) is stable to oxidation even after oxygen has been bubbled through the solution for 20 h [5]. The remarkable strength of the Fe-C(S) bond is also indicated by the two-electron oxidation of FeTPP(CS), without loss of the CS ligand, to form $\text{Fe}(\text{III})\text{TPP}(\text{CS})^+$ whereas FeTPP(CO) loses CO during the removal of the first electron [13].

The general synthetic route to the thiocarbonyl or selenocarbonyl FeTPP complexes involves a relatively easy procedure: $\text{Fe}(\text{III})\text{TPPCl}$ is stirred in benzene under argon in the presence of Fe powder to form Fe^0TPP ; the subsequent addition of $\text{PhCH}_2\text{SCCl}_3$ or $\text{PhCH}_2\text{SeCCl}_3$, affords FeTPP(CS) [6] or FeTPP(CSe) [7] respectively, in very high yields ($\geq 80\%$).

The above reaction is of great interest since various compounds of the formula RSCl_3 exhibit fungicidal activity [e.g., Folpet (a) and Captan (b)]. Their toxicity has been postulated to stem from the generation of free radicals RSCl_2^{\cdot} (which irreversibly attach to the macromolecules of the cell) during the reduction of RSCl_3 by cytochrome P-450 and subsequent formation of $\text{P-450-Fe(II)} \leftarrow \text{C(Cl)SR}$ and $\text{P-450-Fe(II)} \leftarrow \text{CS}$ [6].

The effects on metalloporphyrins of substituents on the porphyrin ring and of axially bound ligands have been studied by a variety of spectroscopic techniques [14,15]. The use of IR spectroscopy has been fairly limited, presumably due to the complexity of the porphyrin spectra. The IR spectra of tetraphenylporphyrin and several tetraphenylpor-

phyrin metal complexes have been reported and partially assigned by Alben et al. [16,17]. The metal-nitrogen stretching vibrations of such complexes, appearing in the far-IR spectra, have also been assigned [18]. In a recent study of the IR spectra of a series of iron tetraphenylporphyrin complexes [19], bands sensitive to spin state and oxidation state were identified. In this chapter, the results of a study of the FT-IR spectra of FeTPP(CX) ($X = S, Se$) and FeTPP(CX)L ($X = S, Se; L = py, EtOH$) will be presented. This investigation was undertaken in order to examine the perturbations induced by the axially bound ligands on the metal-porphyrin interactions.

7.2 Experimental

7.2.1 Sources of Materials

Fe(III)TPPCl was purchased from Strem Chemicals. Samples of FeTPP(CX)L ($X = S, Se; L = EtOH, py$) were obtained from Drs. J.P. Battioni and D. Mansuy (Laboratoire de chimie de L'Ecole Normale Supérieure, Paris, France) or were synthesized utilizing the procedure given in References 6 and 7; the reagents $\text{PhCH}_2\text{XCCl}_3$ ($X = S, Se$) were also obtained from Drs. Battioni and Mansuy. FeTPP(CX) ($X = S, Se$) complexes were prepared by heating FeTPP(CX)(EtOH) at 160°C for 4 h, as described in Reference 6. FeTPP(CO)-

(py) was synthesized according to the literature procedure [4]. CsI (99.999%) was obtained from Aldrich Chemical Co.

7.2.2 Spectroscopic Measurements

The IR spectra of all FeTPP derivatives were recorded for samples pressed into CsI pellets, which were prepared in an argon-purged glove bag. FT-IR spectra were obtained on a Nicolet 6000 Fourier-transform infrared spectrometer (resolution 0.5 cm⁻¹). ¹³C NMR spectra were measured on a Varian XL-200 spectrometer equipped with a broad-band probe. The chemical shifts reported are relative to TMS.

7.2.3 Reaction of FeTPP(CX) (X = S, Se) with CO

FeTPP(CX) (X = S, Se) (20 mg) was dissolved in deaerated spectrograde benzene (10 ml) under argon. The solution was transferred to the high-pressure apparatus described previously (Section 3.2.1) and degassed in three freeze-thaw cycles. The reaction compartment was then pressurized with CO (20 atm). After periods of 6-24 h the CO gas was removed by adsorption on charcoal in a second compartment. The FT-IR spectrum of the solution did not exhibit any peaks in the carbonyl region.

7.3 Results and Discussion

FeTPP(CO)L complexes are quite unstable with a half-life in aerated solution of the order of minutes [5]. The pentacoordinated complex, FeTPP(CO), decomposes virtually instantly on exposure to air [12]. In contrast, the compounds described here are remarkably stable; their half-life in solution is of the order of hours [FeTPP(CX)L] or days [FeTPP(CX)] (X = S, Se; L = py, EtOH) [5-7]. The pentacoordinated FeTPP(CX) (X = S, Se) species are stable in air for years in the solid state. The difference in stability between these complexes and their carbonyl analogues within the above series indicates a decreasing susceptibility of the metal toward oxidation and accordingly decreasing electron density at the metal in the order CO > CSe ≈ CS. This trend may be interpreted in terms of a greater extent of π-back-donation from the metal to the CS or CSe ligand than to CO [20].

The FT-IR spectra of these complexes were obtained to assess the effects of the differences in the bonding properties of the ligands on the metal-porphyrin interaction. The spectra of the porphyrin derivatives studied are shown in Figures 7.2-7.9, and the positions of the major peaks, together with assignments adopted from Alben *et al.* [16,-17], are listed in Table 7.1. The first row of this table

lists the $\nu(\text{CX})$ vibrations, while the remaining frequencies correspond to peaks characteristic of the FeTPP moiety.

Difference spectra represent the simplest method of establishing empirically any perturbations induced by the axial ligands on the porphyrin ring vibrations. In order to illustrate the utility of difference spectra in assessing changes in metal-porphyrin bonding, the spectrum obtained by subtracting the spectrum of Fe(III)TPPCl from that of FeTPP(CSe)(EtOH) is presented in Figure 7.10. The features in this spectrum are the result of a number of factors: the different oxidation and spin states of the iron atom in the two complexes; the lower symmetry of Fe(III)TPPCl due to ring puckering [21]; and the absence of axial π -backbonding in the chloride complex.

The difference spectrum obtained by the subtraction of the spectrum of FeTPP(CS)(py) from that of FeTPP(CSe)(py) is shown in Figure 7.11. The elimination of all porphyrin vibrations in the difference spectrum indicates that the interactions of the CS and CSe ligands with the metal in these systems are similar. Specifically, the comparable extent of metal $d\pi \rightarrow \text{CX } \pi^*$ backbonding in these complexes is demonstrated by this result in that the availability of metal $d\pi$ electron density for donation to the π^* orbitals of the porphyrin is a function of the amount of $d\pi$ electron density transferred to the axial ligands [20]. Therefore,

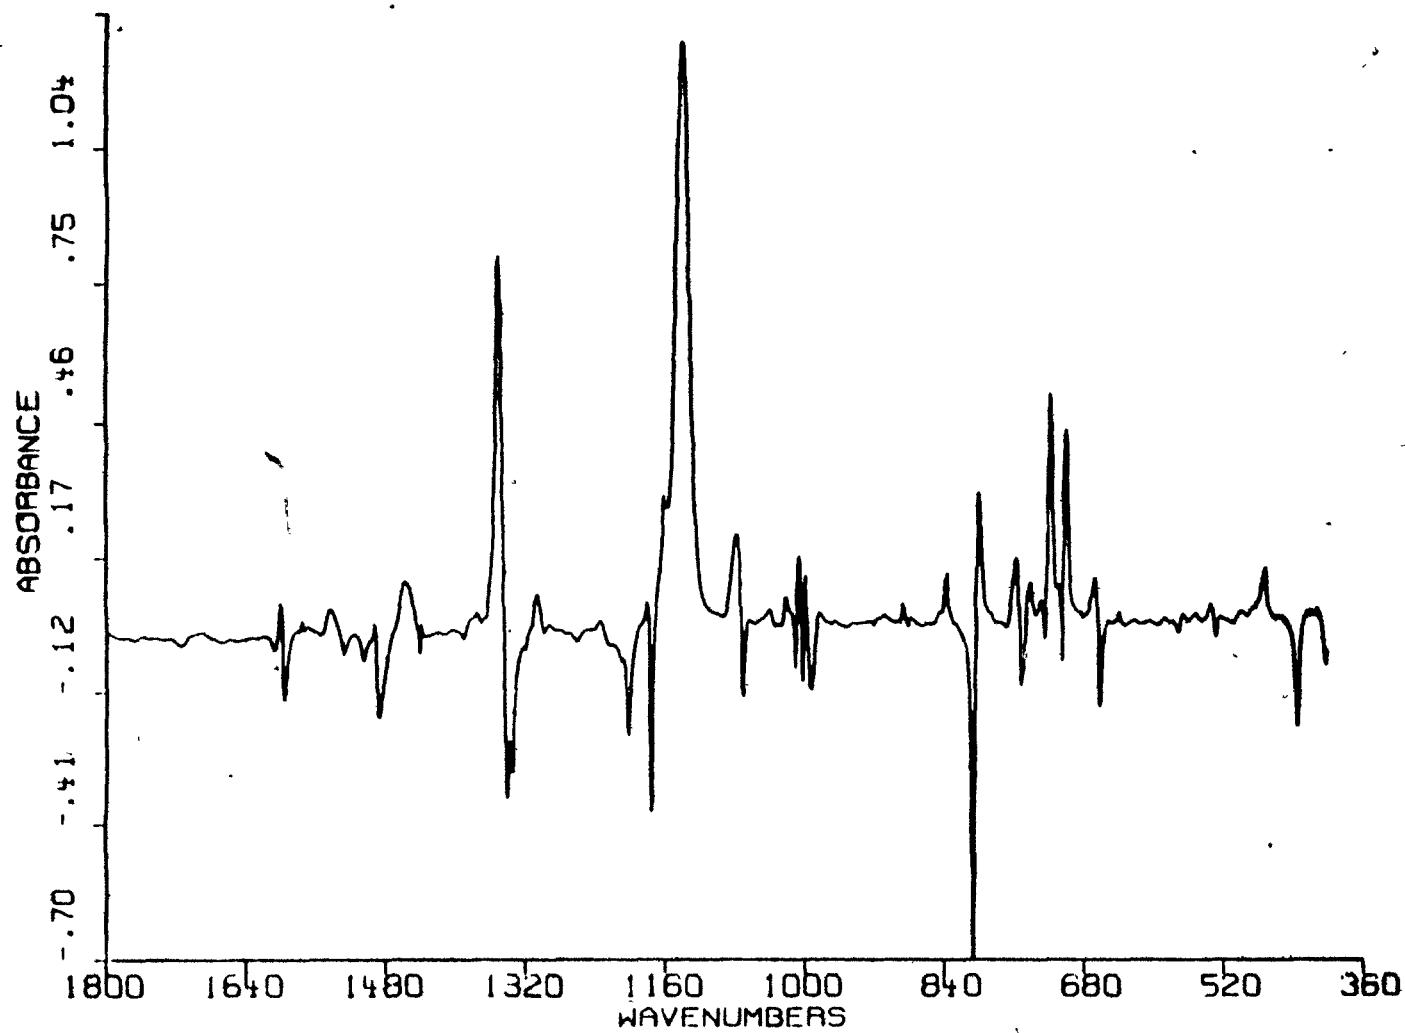

Figure 7.10. Difference spectrum obtained by the subtraction of the FT-IR spectrum of Fe(III)TPPCl from that of FeTPP(CSe)(EtOH).

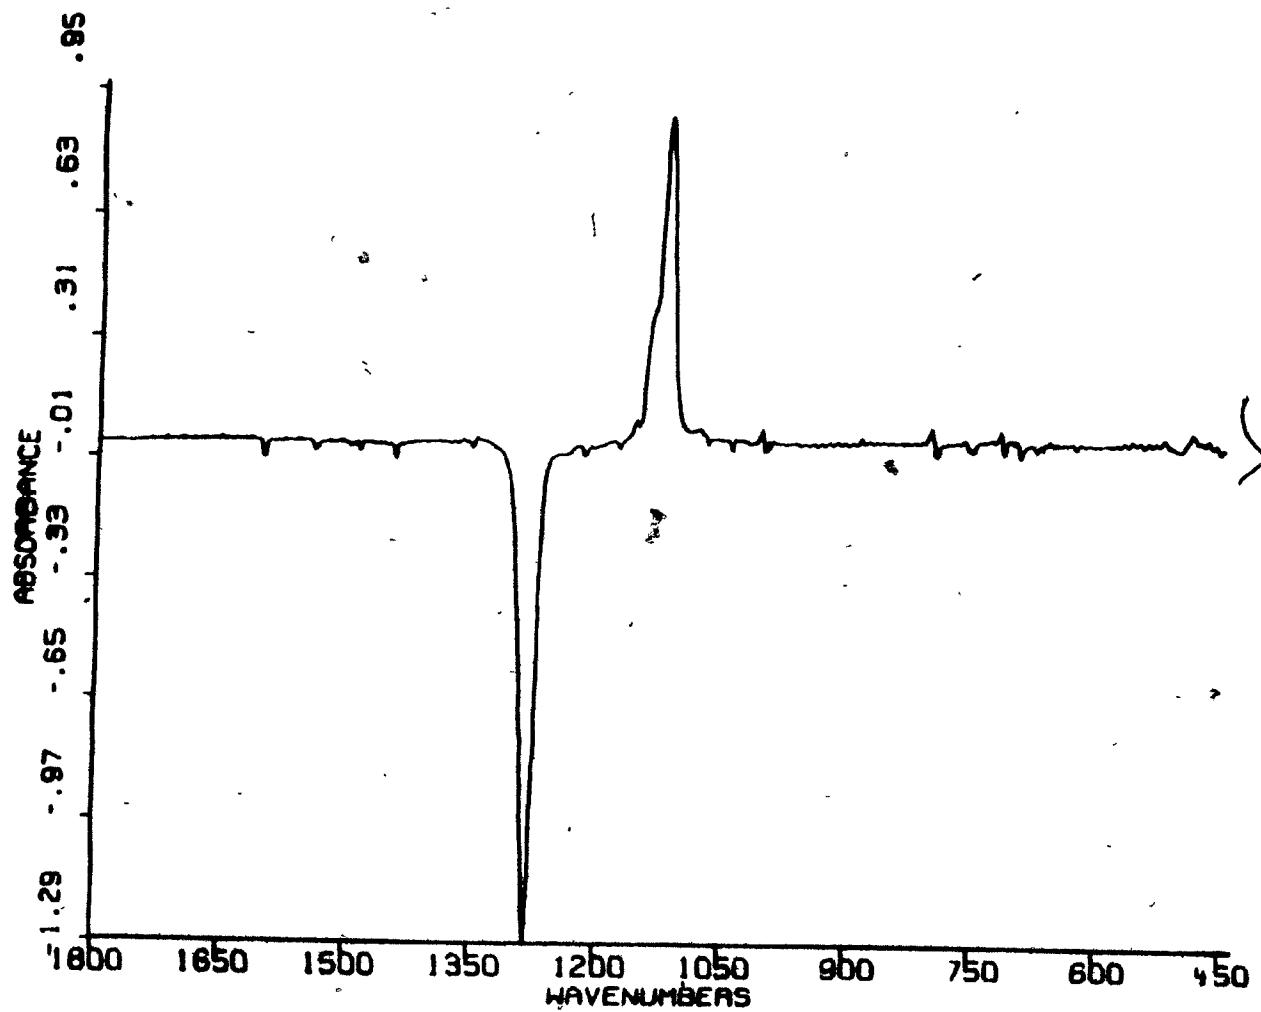

Figure 7.11. Difference spectrum obtained by the subtraction of the FT-IR spectrum of FeTPP(CS)(py) from that of FeTPP(CSe)(py).

any variation in this amount should be reflected in the frequencies of the porphyrin vibrational modes. The difference spectra obtained for the FeTPP(CX)(EtOH) ($X = S, Se$) pair and the pentacoordinated species, FeTPP(CX), also did not exhibit any features due to the vibrational modes of FeTPP.

Figure 7.12 displays the FeTPP(CSe)(py)-FeTPP(CO)(py) difference spectrum. The most significant features are the $\nu(CX)$ modes at 1984 ($X = O$) and 1122 ($X = Se$) cm^{-1} and a peak at 680 cm^{-1} present in the carbonyl complex only. The position of the latter peak suggests its assignment to the Fe-C-O bending mode [22]. No peaks attributable to the Fe-C-X bending modes were observed in the spectra of the thiocarbonyl and selenocarbonyl derivatives. However, these peaks may appear in the region of the spectrum below 600 cm^{-1} , which was not examined, in view of the substantial shift to lower frequencies of M-C-X bending modes with increase in mass of the terminal atom [23]. The difference spectrum in Figure 7.12 and the data in Table 7.1 reveal some small shifts ($< 2 \text{ cm}^{-1}$) in positions of porphyrin vibrational modes in the spectrum of FeTPP(CSe)(py) as compared to that of the carbonyl analogue. The small magnitudes of these shifts suggest a much greater similarity between the selenocarbonyl (or thiocarbonyl) and the carbonyl complex than do the relative stabilities described earlier in this

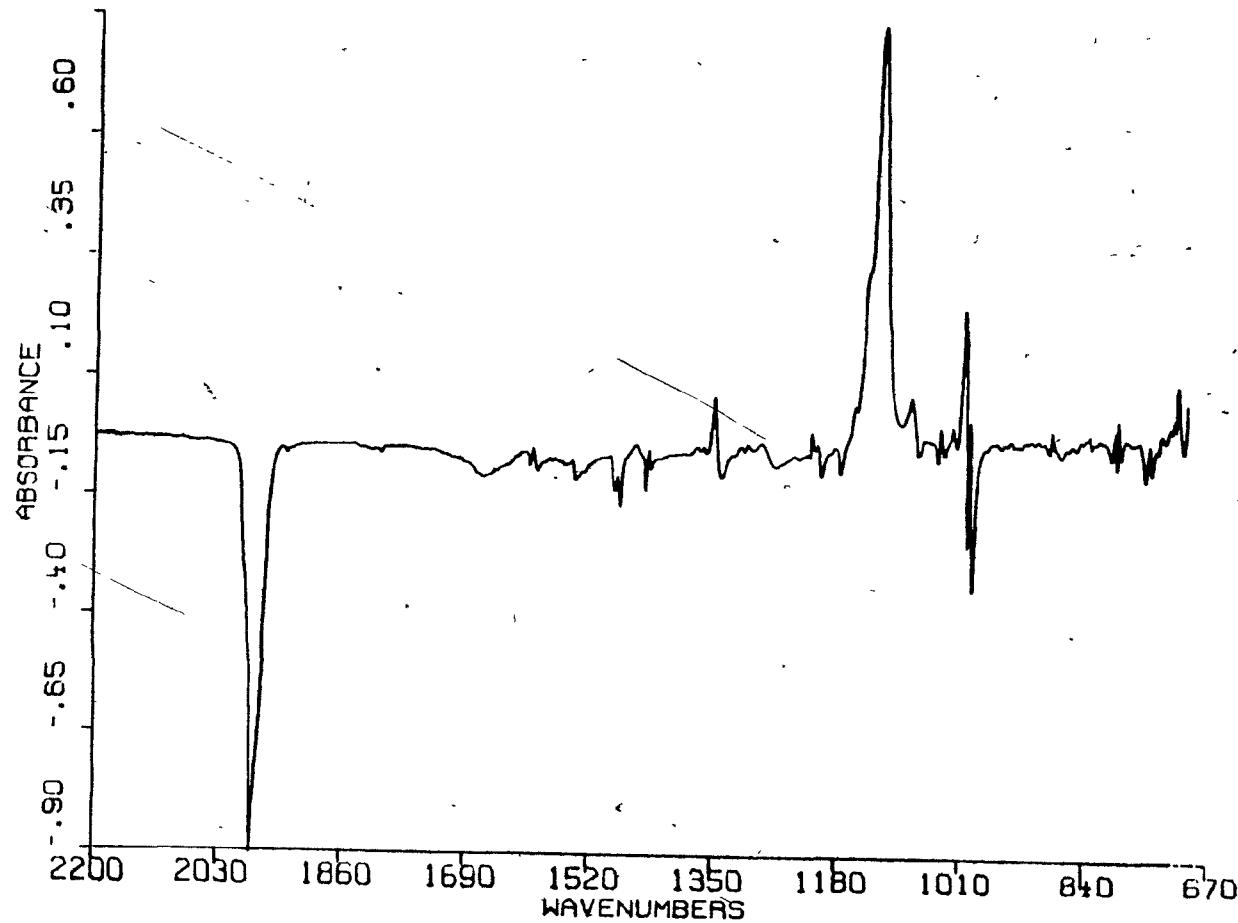

Figure 7.12 Difference spectrum obtained by the subtraction of the FT-IR spectrum of FeTPP(CO)(py) from that of FeTPP(CSe)(py).

section. It thus appears that the differences in M-C(X) bond strengths among the carbonyl, thiocarbonyl and selenocarbonyl FeTPP complexes do not induce sufficient changes in the extensively delocalized π -framework of the porphyrin to give rise to significant shifts in vibrational frequencies.

The subtraction of the spectrum of FeTPP(CSe)(EtOH) from that of the corresponding pyridine derivative (Figure 7.13) reveals several shifts in peaks due to porphyrin vibrational modes. Similar changes are observed in Figure 7.14 where the spectrum of FeTPP(CS)(EtOH) has been subtracted from that of FeTPP(CS). The positive peak in this spectrum at 1175 cm^{-1} represents a peak which appears in the spectra of both complexes but with an enhanced intensity in the spectrum of FeTPP(CS). This increased intensity may be attributed to reduced symmetry of the porphyrin ring in the pentacoordinated complex: an X-ray crystallographic study of FeOEP(CS) has revealed a 0.23- \AA displacement of the iron atom out of the porphyrin plane towards the CS ligand [24]. Comparison of the data in Table 7.1 indicates that the shifts observed in the difference spectra with variation in or removal of the axial ligand L generally follow a consistent trend. The magnitude of the shift of a given peak relative to its position in the spectrum of FeTPP(CX)(py) (X = S or Se) increases in the order FeTPP(CX)(EtOH) < Fe(III)TPPCl < FeTPP(CX), while the direction of the shift

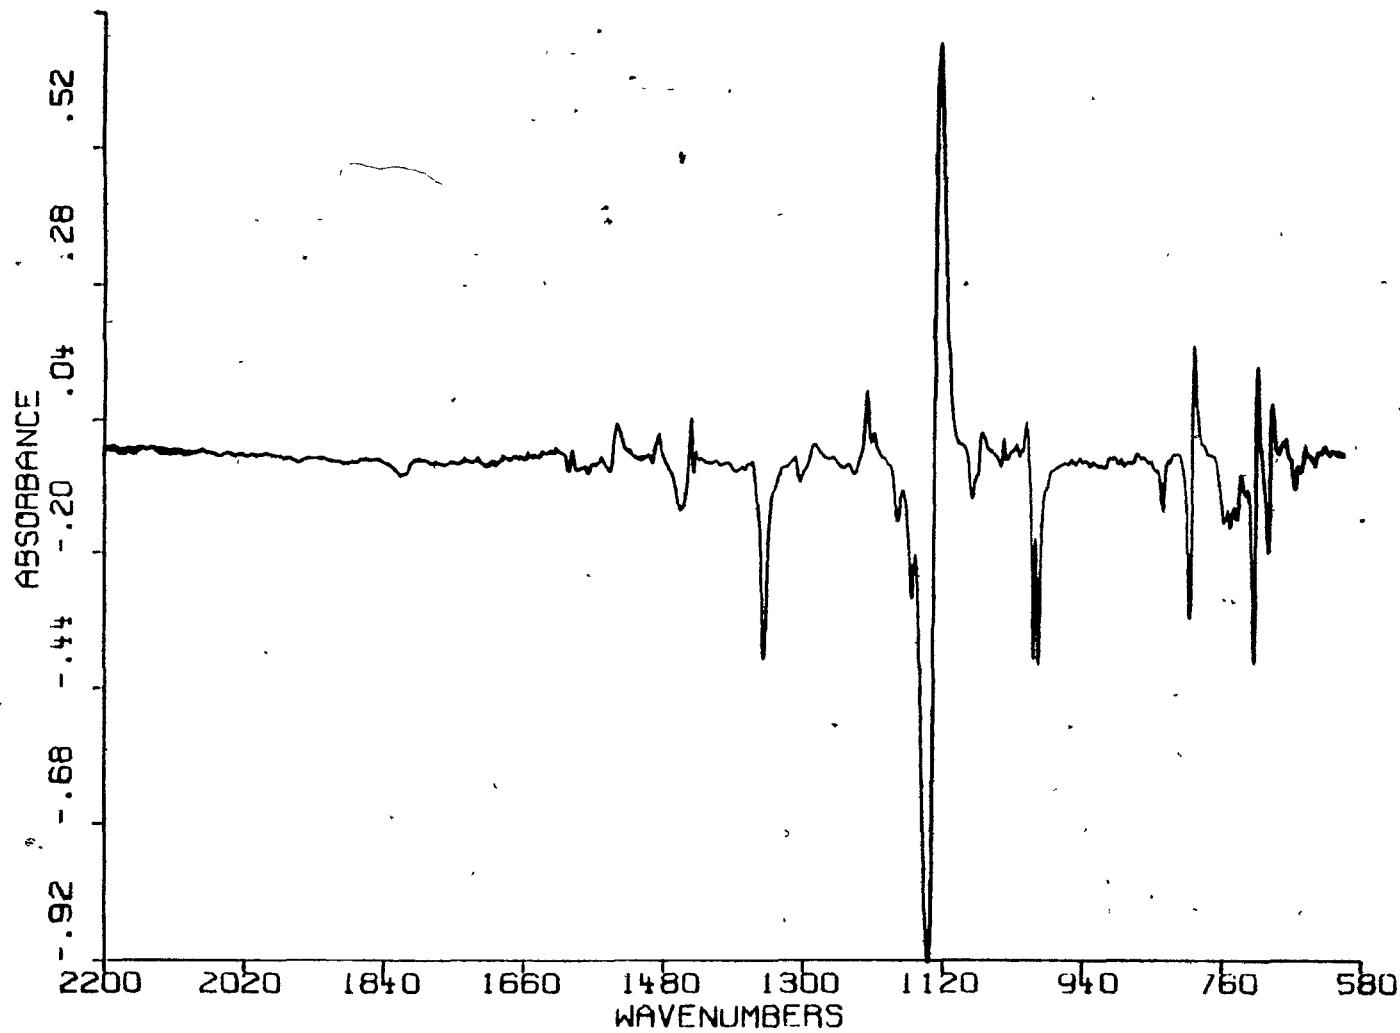

Figure 7.13. Difference spectrum obtained by the subtraction of the FT-IR spectrum of FeTPP(CSe)(EtOH) from that of FeTPP(CSe)(py).

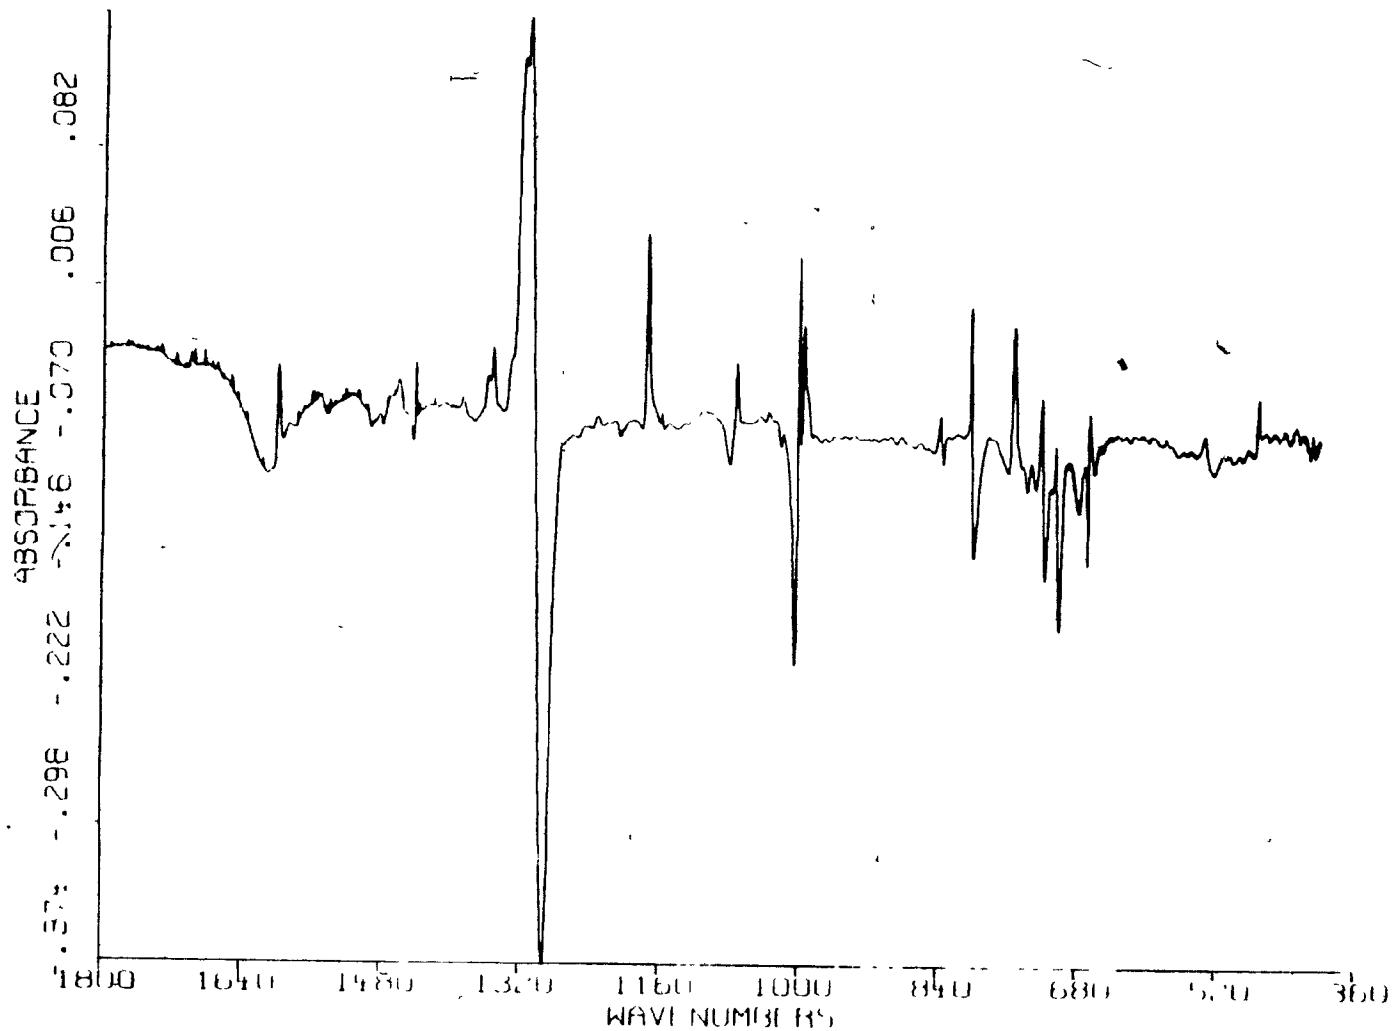

Figure 7.14. Difference spectrum obtained by the subtraction of the FT-IR spectrum of FeTPP(CS)(EtOH) from that of FeTPP(CS).

may be towards higher or lower frequencies. This order appears to parallel the extent of displacement of the iron atom out of the porphyrin plane. For instance, FeTPP(CS)-(py) exhibits planarity of the FeTPP core (data reported in Table II of Reference 25) while 0.23- and 0.38-Å displacements of the iron atom out of the porphyrin plane have been reported for FeOEP(CS) [24] and Fe(III)TPPCl [21], respectively. It is of interest to note that the 1350 cm^{-1} peak remains unshifted in the spectra of all the Fe(II) complexes. This peak has been found to be sensitive to the spin state of the metal [19], and this observation is corroborated in the present study by the appearance of this peak as a shifted doublet in the spectrum of Fe(III)TPPCl at 1340.2 and 1334.1 cm^{-1} . A second peak identified in previous work [19] as oxidation-state sensitive and slightly spin-state sensitive is observed in the $803\text{-}795\text{ cm}^{-1}$ range in the spectra of all the Fe(II) complexes studied here and at 807 cm^{-1} in the spectrum of Fe(III)TPPCl. Among the Fe(II) complexes, this peak shifts to higher frequency on going from FeTPP(CX)(py) to FeTPP(CX)(EtOH) and is further shifted to higher frequency in the spectrum of the penta-coordinated species. Since the shifts of peaks sensitive to oxidation state are generally interpreted in terms of changes in the amount of metal $d\pi$ electron density transferred to the porphyrin π^* orbitals [19], the above data

indicate that the extent of metal to porphyrin π -back-donation in the complexes studied here increases in the order FeTPP(CX) < FeTPP(CX)(EtOH) < FeTPP(CX)(py).

The resonance Raman spectra of FeTPP(CS) and FeTPP(CS)-(py) have been reported, as part of a resonance Raman investigation of a series of iron tetraphenylporphyrin complexes [25]. Spectra were obtained with excitation into both of the characteristic visible absorption bands of porphyrins - the Soret and α, β bands. From the data obtained for the entire series of complexes studied, two bands sensitive to the extent of metal to porphyrin π -back-donation were identified. Both these bands were observed to shift to higher frequency on going from FeTPP(CS)(py) to FeTPP(CS), indicating that less electron density is transferred from the metal to the porphyrin in the pentacoordinated complex, in agreement with the present study. This result was attributed to the displacement of the iron atom out of the porphyrin plane in FeTPP(CS), leading to less favourable overlap of the Fe $d\pi$ orbitals and the porphyrin π^* orbitals than is the case in planar species such as FeTPP(CS)(py) [25].

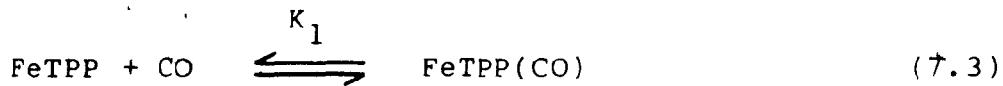

In view of the frequency variations observed between the IR spectra of FeTPP(CX), FeTPP(CX)(py) and FeTPP(CX)(EtOH) for a given X, it is of interest to assess the extent of metal \rightarrow CX π -back-donation in these various complexes.

While differences in carbonyl frequencies can be related to changes in the CO bond order (i.e., the energy-factored force field approximation is valid for $\nu(\text{CO})$ modes) [26], the CS and CSe stretching frequencies cannot serve as direct measures of bond order due to increased mixing of M-C(X) and C-X stretching modes with increase in the mass of X [27]. This effect was noted in a study of M(II)OEP(CS)(py) (M = Fe, Ru, Os) [8], and data for FeOEP(CS) were found not to fit the relationship between $\nu(\text{CS})$ and the C-S bond distance established for a series of thiocarbonyl derivatives [24] (see Table 2.3). However, a trend in $\nu(\text{CX})$ values among a series of related compounds can generally be considered to reflect variations in $M \rightarrow CX$ π -backbonding. It can be seen in Table 7.1 that substitution of a pyridine ligand by an ethanol ligand results in an increase in $\nu(\text{CX})$ ($X = S, Se$), indicating that when the trans ligand is ethanol less electron density is donated to the metal. The higher $\nu(\text{CX})$ for the pentacoordinated complexes is indicative of a further decrease in the net electron density at the metal. The trend in $\nu(\text{CX})$ frequencies thus suggests that the availability of metal electron density for π -back-donation to the porphyrin decreases in the order FeTPP(CX)(py) > FeTPP(CX)-(EtOH) > FeTPP(CX). This finding is consistent with the conclusions reached after examination of the porphyrin vibrational modes in both the IR and resonance Raman spectra.

An attempt was made to coordinate a CO ligand trans to CX ($X = S, Se$) in the pentacoordinated FeTPP(CX) complexes [Eq. 7.2], since the frequencies of the $\nu(\text{CO})$ modes of the FeTPP(CO)(CX) complexes would provide a quantitative measure of the extent of $d\pi$ electron density transferred to the CX ligands.

The reactions represented by Eq. 7.2 did not take place even at CO pressures of 20 atm, while the corresponding reaction of FeTPP(CO) under less than 1 atm CO pressure yields $\text{FeTPP}(\text{CO})_2$ [12]. However, the latter complex undergoes facile CO loss. The equilibrium constants for the formation of the monocarbonyl and dicarbonyl complexes by the following reactions:

have been reported [12]. K_1 [$(6.6 \pm 0.3) \times 10^4$] was found to be much greater than K_2 (140 ± 3) in direct contrast with the corresponding reaction of deuteroheme (H) with pyridine

where K_1 for the formation of $H(py)$ is substantially smaller than K_2 for the formation of $H(py)_2$ [28]. The lower affinity of the iron atom for CO after binding of one CO ligand has been attributed to the decreased availability of Fe d π electron density for π -back-donation to CO after formation of the first Fe-CO bond [12]. This is manifested in the substantially higher $\nu(CO)$ value for $FeTPP(CO)_2$ as compared to that of $FeTPP(CO)$ [12]. Since it is well established that both the CS and CSe ligands are stronger π -acceptors than CO [9], the lack of CO incorporation into the $FeTPP(CX)$ complexes (i.e., K_t [Eq. 7.2] < K_2) is not unexpected.

As part of the present study, the ^{13}C NMR spectra of $FeTPP(CX)$ ($X = S, Se$) and $FeTPP(CS)(py)$ were recorded. The positions of the resonances are listed in Table 7.2, together with the corresponding values from the literature for $FeTPP(CX)(EtOH)$ [6,7]. Comparison of the chemical shift for the CX resonance of $FeTPP(CX)$ with that for $FeTPP(CX)-(EtOH)$ reveals an upfield shift in the pentacoordinated species. The CS resonance of $FeTPP(CS)(EtOH)$ is in turn upfield from that of $FeTPP(CS)(py)$. It has been established in studies of the ^{13}C NMR spectra of metal chalcocarbonyl complexes that an upfield shift in the position of a CX ($X = O, S, Se$) resonance is indicative of a decrease in the extent of metal to chalcocarbonyl π -back-donation [29,30].

Table 7.2. ^{13}C NMR Chemical Shifts of FeTPP(CX) and FeTPP(CX)(L) Complexes (X = S, Se)^{a,b}

Accordingly, the trends in the CX resonances reported above are consistent with the trends observed in the $\nu(\text{CX})$ frequencies in the IR spectra. The other peaks listed in Table 7.2 exhibit very small shifts with variation in the axial ligands. In particular, it may be noted that replacement of a CS ligand by a CSe ligand in a given complex has virtually no effect on the ^{13}C NMR spectrum of the FeTPP moiety.

Summary and Contributions to Knowledge

1. Arene displacement from $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S}$, Se) complexes by ligands other than CO has been studied for the first time and has provided a route to the synthesis of chromium thiocarbonyl and selenocarbonyl derivatives containing more than one monodentate ligand (other than CO) or a tridentate ligand. The reaction of $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S}$, Se) complexes with excess $(\text{RO})_3\text{P}$ ($\text{R} = \text{Me}$, Et , n-Bu , Ph) afforded $\text{Cr}(\text{CO})_2(\text{CX})[(\text{RO})_3\text{P}]_3$ in high yield. The products were identified as mixtures of isomers consisting predominantly of the mer I isomer, in which a phosphite ligand is trans to CX, together with a small amount of the fac isomer. Very small amounts of the mer II isomer, in which a phosphite ligand is trans to CO, were detected in the ^{31}P NMR spectrum of $\text{Cr}(\text{CO})_2(\text{CX}) - [(\text{MeO})_3\text{P}]_3$. Arene displacement from $(\text{bz})\text{Cr}(\text{CO})_2(\text{CX})$ by the tridentate ligands triphos-U $[(\text{Me})\text{C}(\text{CH}_2\text{P}(\text{Ph})_2)_3]$ and triphos $[(\text{Ph}_2\text{PCH}_2\text{CH}_2)_2\text{PhP}]$ yielded, respectively, $(\text{triphos-U})\text{Cr}(\text{CO})_2(\text{CX})$ as the fac isomer and $(\text{triphos})\text{Cr}(\text{CO})_2(\text{CX})$ as a mixture of two fac isomers.
2. The crystal structures of the mer I isomers of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}$, Se) were obtained.

3. The ^{31}P NMR spectra of the complexes mentioned in 1 above were recorded. These presented the first opportunity to compare the ^{31}P resonances of tertiary phosphite and tridentate phosphine ligands cis and trans to CO, CS and CSe ligands in Group VIB metal complexes.
4. $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{O}, \text{S}, \text{Se}$) complexes were found to undergo intramolecular isomerization. The rate of isomerization was established to be fastest for the selenocarbonyl complex and slowest for the tricarbonyl complex.
5. Activation parameters were calculated for the fac \leftrightarrow mer isomerization of $\text{Cr}(\text{CO})_3[(\text{MeO})_3\text{P}]_3$ and the fac \leftrightarrow mer I isomerization of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$).
6. In one of the few applications to date of two-dimensional NMR spectroscopy in the study of stereochemically nonrigid organometallic complexes, the interconversion of mer I and mer II isomers was observed in the 2-D NOE ^{31}P NMR spectra of $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$). Analysis of these spectra established that the observed processes involved a trigonal prismatic twist rather than a bicapped-tetrahedron mechanism.

7. Kinetic studies of arene displacement from (bz)- $\text{Cr}(\text{CO})_2(\text{CX})$ ($\text{X} = \text{S}, \text{Se}$) by $(\text{MeO})_3\text{P}$ demonstrated that the reaction rate is first order with respect to the incoming ligand and first order in complex. These reactions were proposed to proceed by the same ring slippage mechanism postulated for arene displacement from $(\eta\text{-Arene})\text{M}(\text{CO})_3$ ($\text{M} = \text{Mo}, \text{W}$) complexes. The relative rates of arene displacement from (bz) $\text{Cr}(\text{CO})_2(\text{CX})$ by $(\text{MeO})_3\text{P}$ and of fac + mer I isomerization of the $\text{Cr}(\text{CO})_2(\text{CX})[(\text{MeO})_3\text{P}]_3$ product were found to be consistent with the possibility that the fac isomer is the initial product of the reaction and subsequently isomerizes to the observed mer I product.

8. The rate of arene displacement from (bz) $\text{Cr}(\text{CO})_2(\text{CSe})$ by $(\text{MeO})_3\text{P}$ was found to be faster than that for the corresponding thiocarbonyl complex. On the basis of comparison of the activation parameters calculated for these reactions, this result was attributed to less crowding in the activated complex in the selenocarbonyl case.

9. The effects on the rate of arene displacement from $(\eta\text{-Arene})\text{Cr}(\text{CO})_2(\text{CS})$ complexes of size and nucleophilicity of the incoming ligand and of substituents on the arene were investigated.

10. The feasibility of a procedure for estrogen receptor assay based on the detection by FT-IR spectroscopy of Cr(CO)₃-labelled modified estradiol bound to estrogen receptors in target tissue was examined. The sensitivity of the FT-IR measurements proved sufficient for detection of the metal carbonyl label but not for its quantitative determination.
11. The FT-IR spectra of (5,10,15,20-tetraphenylporphinato)iron(II) (FeTPP) complexes containing axially bound chalcocarbonyl ligands were recorded. Difference spectra obtained by subtraction of spectra of pairs of complexes in the series FeTPP(CX) (X = S, Se) and FeTPP(CX)L (X = S, Se; L = py, EtOH) were examined in order to assess the perturbations of the vibrational modes of the porphyrin ring with variation in the axial ligands.
12. FeTPP(CX) (X = S, Se) was found not to bind CO at its vacant coordination site under 20 atm CO pressure, demonstrating a substantial withdrawal of Fe d π electron density by the CX ligands.

Suggestions for Future Work

In Chapter 3 of this thesis, an example of the use of two-dimensional NMR spectroscopy in the study of stereochemical nonrigidity of organometallic complexes was described. This investigation, which represents one of the few applications to date of 2-D NMR spectroscopy in organometallic chemistry, demonstrated that 2-D NMR measurements can be employed not only to establish the occurrence of a chemical exchange process but also to elucidate rearrangement mechanisms. Accordingly, further studies by 2-D NMR spectroscopy of stereochemically nonrigid organometallic complexes are clearly worthwhile.

Further investigations of the rearrangement processes of $\text{Cr}(\text{CO})_2(\text{CX})\text{L}_3$ ($\text{X} = \text{O}, \text{S}, \text{Se}$) complexes should be undertaken. It would be of interest to assess, through the study of a variety of ligands, the effects of electronic and steric factors on the equilibrium distribution of $\text{Cr}(\text{CO})_2(\text{CX})\text{L}_3$ isomers and on the activation parameters for intramolecular isomerization. The synthesis of complexes of the type $\text{Cr}(\text{CO})_2(\text{CS})(\text{L})_2\text{L}'$ would allow chemical exchange between fac isomers to be studied by 2-D NMR spectroscopy. The results of the present study suggest that interconversion between the fac and mer I or mer II isomers of $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$ ($\text{X} = \text{S}, \text{Se}$) is too slow to be observed by 2-D ^{31}P NMR spectroscopy but that the replacement of the $(\text{MeO})_3\text{P}$

groups by ligands that minimize steric effects as well as possess electronic properties comparable to those of CX ligands may accelerate the rates of these processes. In addition, the application of 2-D ^{13}C NMR spectroscopy in these systems should be investigated since ^{13}C nuclei in most organometallic complexes relax slower than ^{31}P nuclei, thus allowing slower rearrangement processes to be observed by 2-D ^{13}C NMR. Such studies would be facilitated by ^{13}C -enrichment, which could be readily achieved by photochemical substitution of carbonyl groups by ^{13}CO in the (η -Arene)- $\text{Cr}(\text{CO})_2(\text{CX})$ precursors to the $\text{Cr}(\text{CO})_2(\text{CX})\text{L}_3$ complexes.

APPENDICES

Appendix A

Structural Characterization of the mer I Isomer of
 $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$: X-Ray Data Collection,
Structure Solution and Refinement

The unit cell and data collection parameters are summarized in Table A.1. Weissenberg and precession photographs showedmmm symmetry and the systematic absences: on $0kl$, $k = 2n + 1$, on $h0l$, $l = 2n + 1$, and on $hk0$, $h = 2n + 1$, which uniquely define the space group 'Pbca' (No. 61, D_{2h}^{15}). The accurate unit cell dimensions were obtained by automatic centering of 51 reflections scattered randomly in reciprocal space in the range $15^\circ < 2\theta < 25^\circ$. The following formulas were used in the data reduction

$$I = N - B(t_s/t_b), \quad \sigma(I) = [N + B(t_s/t_b)^2]^{1/2},$$

$$L_p = \frac{(\sin 2\theta)(\cos^2 2\theta_m + 1)}{(\cos^2 2\theta + \cos^2 2\theta_m)}.$$

The net intensity I is derived from the total count N accumulated during the scan time t_s . The background count

B was measured for time t_b . The Lorentz-polarization correction L_p is calculated for diffraction angles $2\theta_m$ and $2\theta_s$ at the monochromator and sample crystals, respectively.

The structure was solved by conventional heavy atom techniques and refined using the block-diagonal least-squares approximation. In the last stages of the refinement all atoms were refined with anisotropic thermal parameters. A final difference Fourier map was devoid of significant features; the highest peaks were about 1% of the intensity for the last carbon atom found and were randomly located. Also, since there appeared to be no clear indication of hydrogen atom locations, these atoms were not included in the structure factor calculations.

The computer programs used for the data collection, structure solution and refinement and geometry calculations are those contained in the N.R.C. PDP-8e crystallographic package [1]. The perspective diagram was prepared by the Concordia University CDC Cyber system. The function minimized in the least-squares refinement was

$$\sum w(|F_o| - |F_c|)^2 \quad \text{where } w = 1/[(\sigma(F))^2 + 0.03F^2].$$

The discrepancy indices listed in Table A.1 are:

$$R_F = [\sum (|F_O| - |F_C|)^2 / \sum |F_O|^2]$$

$$R_{WF} = [\sum w(|F_O| - |F_C|)^2 / \sum |F_O|^2]^{1/2}$$

$$GOF = [\sum w(|F_O| - |F_C|)^2 / (m-n)]^{1/2}$$

The neutral atom scattering factors and anomalous dispersion corrections were taken from standard listings [2]. The observed and calculated structure factors are listed in Table A.2. The final positional parameters are collected together in Table A.3. The final thermal parameters appear in Table A.4.

Table A.1. Crystallographic Data for X-ray Diffraction Study of
 $\text{Cr}(\text{CO})_2(\text{CS})[(\text{MeO})_3\text{P}]_3$

Crystal Parameters

crystal system = orthorhombic calcd density = 1.466 g cm⁻³
 space group = Pbca obsd density = 1.40(2) g cm⁻³
 a = 15.61(1) Å temp = 295 K
 b = 15.32(2) Å formula = $\text{C}_{12}\text{H}_{27}\text{O}_1\text{iSP}_3\text{Cr}$
 c = 18.88(1) Å mol wt = 524.0 g mol⁻¹
 v = 4505 Å³
 z = 8

Measurement of Intensity Data

diffractometer = Picker Nuclear FACS-1
 radiation = Mo K α
 monochromator = highly oriented graphite
 detector aperture = 3 mm X 3 mm
 crystal to detector distance = 25 cm
 detector = scintillation counter and pulse height analyzer set for
 100% of Mo K α peak
 attenuators = Ni foil used for intensities $> 10^4$ Hz
 scan type = coupled θ (cryst) -20 (detector), 2.0° min⁻¹
 scan length = $(2\theta) = [1.8 + (0.692 \tan \theta)]^\circ$, beginning 0.9° below
 the predicted peak
 rotation axis [0 1 0]
 reflections measured = +h, +k, +l
 min and max $2\theta = 3.5^\circ, 40.0^\circ$
 stds every 50 cycles = 4 3 0, 0 0 6, 0 4 3
 variation = +3% (random)
 number of reflections collected = 2108
 no. with $I > 3\sigma(I)$ = 1453
 $R_F = 5.06\%$
 $R_{WF} = 7.30\%$
 $GOF = 1.19$

Structural Characterization of the mer I Isomer of
 $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$: X-Ray Data Collection, Structure
 Solution and Refinement

Table B.1. Crystallographic Data for X-ray Diffraction Study of
 $\text{Cr}(\text{CO})_2(\text{CSe})[(\text{MeO})_3\text{P}]_3$

Crystal Parameters

crystal system = orthorhombic

space group = Pbca

calcd density = 2.396 g cm^{-3}

$a = 15.483(3) \text{ \AA}$

temp = 118 K

$b = 15.213(5) \text{ \AA}$

formula = $\text{C}_{12}\text{H}_{27}\text{O}_{11}\text{SeP}_3\text{Cr}$

$c = 18.997(3) \text{ \AA}$

mol wt = 570.9 g mol^{-1}

$V = 4474.6 \text{ \AA}^3$

$Z = 8$

Measurement of Intensity Data and Structure Solution

Enraf-Nonius CAD-4 diffractometer at 118 K , coupled to a VACS SDP computing system

lattice parameters by least-squares refinement of 25 medium-angle settings

range of hkl : $h 0-16, k 0-18, l 0-22$

$\omega/2\theta$ scan

graphite-monochromated MoKa radiation

4 standard reflections ($2\bar{2}6, 0010, 460, 800$): 1% variation (72.1 h exposure)

4398 unique reflections measured, 3091 with $I > 3\sigma(I)$ used intensities corrected for Lorentz and polarization effects and for absorption

structure solved by Patterson and Fourier methods, full-matrix least-squares anisotropic refinements (254 variables) with the H atoms being included in the structure factor calculations but not refined

$R_F = 0.042$

$R_{WF} = 0.062$

Starred atoms were refined isotropically.
 Anisotropically refined atoms are given in the form of the
 isotropic equivalent thermal parameter defined as:

$$(4/3) [a^2AB(1,1) + b^2AB(2,2) + c^2AB(3,3) + ab(\cos \gamma)AB(1,2)$$

$$+ ac(\cos \beta)AB(1,3) + bc(\cos \alpha)AB(2,3)]$$

033	0.010(2)	0.015(2)	0.022(2)	-0.003(2)	-0.002(2)	-0.001(2)
C33	0.013(3)	0.021(3)	0.030(3)	-0.005(2)	-0.007(2)	-0.001(2)

The form of the anisotropic thermal parameter is:
 $\exp[-2\pi i 2\bar{a}2U(1,1) + k\bar{b}\bar{b}2U(2,2) + 12\bar{c}2U(3,3) + 2\hbar k a b U(1,2) + 2\hbar l a c U(1,3) + 2\hbar k b c U(2,3)]$ where a,b, and c are reciprocal lattice constants.

Appendix CCo-adding and Permanent Storage of Large Number of FT-IR Scans

The following is a listing of a program (named LWA) written as a macro compatible with the Nicolet FT-IR software. The program was created in order to overcome the problem of insufficient data collection due to correlation drifting inherent in the collection of large numbers of FT-IR scans. It enables any convenient number of scans to be collected at a time and stored in specified destination files prior to co-addition and subsequent transfer to the permanent storage disk.

OMD

THIS MACRO COLLECTS, CO-ADDS AND STORES INTERFEROGRAMS FOR MULTIPLE SAMPLES
QIT = 3

OMD

ENTER NUMBER OF SAMPLES
