1. Introduction

Lipid droplets (LDs), also called lipid bodies, are dynamic intracellular organelles that contain a core in rich neutral lipids, such as triglycerides (TG) and cholesteryl esters [1]. Their surface is composed of a phospholipid monolayer with a unique phospholipid and fatty acid composition [2]. Initially considered as inert neutral lipid-storage compartments, LDs have become intensively studied organelles, implicated, for example, in the pathology of atherosclerosis, obesity, insulin resistance, type 2 diabetes [3], hepatic steatosis [4], cardiovascular disease, and inflammatory disorders [5,6]. The formation of LDs is a precisely regulated and inducible process which can be triggered by a variety of extracellular cues such as growth factors, long-chain fatty acids [7], oxidized low density lipoproteins [8] or by various environmental insults such as oxidative stress [9,10] and inflammatory stimuli [11]. LDs are rapidly induced under inflammatory conditions in leukocytes. In experimental models of sepsis, the interaction of bacterial lipopolysaccharide (LPS) with Toll-like receptor 4 (TLR4) leads to a considerable accumulation of LDs in macrophages [12]. LDs were shown to contain esterified arachidonic acid in their phospholipid and neutral lipid pools and proposed to be intracellular sites involved in the metabolism of arachidonic acid into eicosanoids [13,14]. Cytosolic phospholipase A2-α (cPLA2-α), also called group IVA PLA2, is a central enzyme for the release of arachidonic acid from phospholipids and has been found to co-localize with LDs [15]. cPLA2-α activation and release of proinflammatory lipid mediators are regulated by TLR4 signaling in LPS-activated macrophages [16].

The surface of LDs is coated with various proteins, many of which regulate their formation, growth or turnover [17]. Members of the PAT family proteins, namely perilipin, adipocyte differentiation-related protein (ADRP) and tail-interacting protein 47 kDa (TIP47),
share extensive amino acid sequence in their amino termini (PAT domain) and bind to LDs [17]. A recently implemented new nomenclature for the PAT proteins has changed the names of perilipin, ADRP and Tip 47 to perilipin 1, 2 and 3, respectively [18]. Perilipin-2 (ADRP) and perilipin-3 (Tip 47) are ubiquitously expressed in different cell types, including macrophages [19,20]. Perilipin-2 is a prominent LD-associated protein, whose expression level rises concomitantly with an increase in both LD abundance and TG level [21]. Perilipin-2 is a key regulator of LD formation and has been investigated in the context of metabolic syndrome and inflammatory diseases [5].

The present study sought to advance our understanding of the physiological roles of perilipin-2 and LDs in microglia, the resident macrophage population of the central nervous system (CNS) [22]. Microglia are of myeloid origin and share certain phenotypic characteristics with macrophages in their activated form. Upon activation microglia express cell surface markers that are also present on macrophages [23]. They respond rapidly to pathological challenges in the CNS by acquiring a reactive state and secreting proinflammatory cytokines, nitric oxide (NO) and reactive oxygen species [22,24]. Importantly, TLR4-initiated signaling underlies microglia-induced inflammation in the CNS [25]. LPS-induced activation of TLR4 triggers an activating downstream signal to mitogen-activated protein kinases (MAPK), c-Jun N-terminal kinase (JNK) and p38 [25]. Phosphorylation of p38 and JNK by upstream MAPK kinases leads to activation of transcription complex activator protein −1 (AP-1), which then induces the expression of proinflammatory cytokines [26]. In LPS-treated macrophages, stimulation of the binding of AP-1 to the Ets/AP-1 binding site results in increased perilipin-2 expression [27]. Although the effect of LPS on perilipin-2 protein expression in macrophages has been previously examined [27,28], this has not been investigated in microglia.

In the current study, we investigated the effects of LPS on LD status and perilipin-2 expression in murine N9 microglia cells. These cells express TLR4 and many other pathogen recognition receptors and rapidly respond to bacterial endotoxins [29]. The effect of LPS was compared with that of oleic acid (OA), a major plasma fatty acid [30]. In cells, OA is esterified and stored as triglyceride inside LDs. OA and other long chain fatty acids induce LD formation and perilipin-2 expression [7,31]. In the brain, OA is synthesized by astrocytes and acts as a neurotrophic factor for neurons [32]. Although induction of LD formation and perilipin-2 expression in response to OA has been assessed in different cell types, it has not been studied so far in microglia.

We hypothesized that stimulation of microglia with LPS may alter LD status and perilipin-2 expression via JNK and/or p38 MAPK. We show that LPS stimulation greatly increases microglial LD and TG content and induces perilipin-2 expression. We also demonstrate that pharmacological inhibition of p38 downregulates perilipin-2 expression and LD accumulation. OA-driven LD accumulation was not accompanied by p38 or JNK activation. In order to better understand the role of microglial LDs in the production of proinflammatory lipid mediators, we examined colocalization of CPLA2-α with LDs. Our findings imply that LPS-driven changes in LD biogenesis and perilipin-2 expression could contribute to microglia-mediated inflammation in the CNS.

2. Materials and methods

2.1. Lipidomics analysis

Lipid analysis was performed as previously reported [33]. Prior to lipid extraction, internal standards were added corresponding to each lipid class, lipids were then extracted from whole cells by a modified Bligh and Dyer method, samples were dried under nitrogen and resuspended in chloroform. Immediately prior to injection the extracted lipids were combined with 2:1 methanol:chloroform with 0.1% (v/v) ammonium hydroxide. This was injected directly into a Q-TOF 2 mass spectrometer (Waters, Milford, MA) using a nano-esi spray source at 1 μl/min. Spectra were obtained in positive-ion mode (PC + H+, TAG + NH4+ ) and negative-ion mode (FAA-H-, PA-H+, PE-H+, PG-H+, PI-H-, PS-H2O+). Acquired spectra were centroided using the Masslynx software then deconvoluted and deisotoped with excel macros.

2.2. Cell culture and treatments

Murine N9 microglia were cultured in Iscove’s Modified Dulbecco’s Medium (IMDM) (+ L-glutamine, + 25 mM HEPES) (Gibco) supplemented with 5% (v/v) fetal bovine serum (FBS) (Gibco) and 1% (v/v) penicillin/streptomycin (Gibco). Subconfluent cells were treated with lipopolysaccharides (LPS) (Escherichia coli, strain O55:B5) (Sigma, #62326) in medium containing 1% FBS as described in the figure legends. In experiments with oleic acid, control group cells were treated with bovine serum albumin (BSA) alone (0.1% w/v). Pharmacological inhibitors SP600125 (Calbiochem, #420119), SB203580 (Sigma, S8307) and LY294002 (Cell Signaling, #9901) were added 30 min prior to the addition of LPS (10 μg/ml). For every 10 μM of SP600125, 0.1% of DMSO was added to the cultures, as recommended by the supplier.

2.3. OA/BSA complex preparation

OA/BSA complex was formed by mixing 30 mg of sodium oleate (Nu-Check Prep, S-1120) with fatty acid-free BSA solution (5% w/v) (Sigma, A6003) for 5 h at 37 °C. After the incubation, the pH of the solution was adjusted to pH 7.4 and the solution was filtered through a 0.22 μm filter. Non-esterified OA concentration in this solution was determined with the NEFA C method kit (Wako). The final molar ratio of OA to BSA was approximately 4.4:1. Aliquots of the stock solution were stored at −20 °C.

2.4. Staining of lipid droplets

LDs in cells fixed with 4% paraformaldehyde were stained with the neutral lipid-staining fluorophores BODIPY 493/503 (4,4-difluoro-1,3,5,7,8-pentamethyl-4-bora-3a,4a-diaza-s-indacene) (Invitrogen, D-3922) or HCS LipidTOX (Invitrogen, H34477). Stock solution of BODIPY 493/503 was made by dissolving the powder in DMSO. Protected from light cells were incubated with BODIPY 493/503 (20 μM, diluted in PBS) for 10 min or with HCS LipidTOX (1:200 in PBS) for 30 min at room temperature. Cells were washed at least twice with PBS.

2.5. Confocal microscopy

Images were acquired with a Zeiss LSM 510 NLO inverted confocal microscope using a Plan Achromat 63X/1.4 Oil DIC objective. Microglial cells were seeded on confocal chamber slides (Lab-Tek, Nalge Nunc International, Rochester, NY, USA) at a density of 1.5 × 104 cells/well (area of well = 0.8 cm2) or on coverslips (area = 1.1 cm2) at a density of 2 × 104 cells/coverslip. Surfaces were coated with rat tail collagen (Sigma, C7661) prior to seeding. Coverslips were mounted on glass microscope slides (Fisher Scientific, 12-550-14) using glycerol-free mounting media Vectashield H-1000 (Vector) and were sealed around the perimeter with clear nail polish. Images of BODIPY 493/503-labeled LDs were acquired using an Argon 488 nm excitation laser and a 500–550 band pass (BP) filter. HCS LipidTOX-labeled LDs were detected using the HeNe 633 nm laser and a long pass (LP) 650 filter. Alexa Fluor 594 (red) was detected using HeNe 543 excitation laser and BP 565–615 IR filter. Each Z-stack image consisted of 10 to 20 optical slices taken at 0.3 μm intervals and had dimensions of 73.1 × 73.1 × 5.7 μm (x, y, z) when zoomed by a factor of 2, and 97.5 × 97.5 × 5.7 μm (x, y, z) when...
2.9. Immunocytochemistry of perilipin-2 and cPLA2-α

Microgla were seeded at a density of 1.5 × 10⁴ cells/well on coverslips (Fisher) coated with rat tail collagen (Sigma, C7661). Paraformaldehyde-fixed cells were permeabilized with Triton X-100 (0.1%) (Amersham Biosciences, # 17-1311-01) for 5 min and blocked with goat serum (10%) (Sigma, G9023) for 1 h for perilipin-2 or 2 h for cPLA2-α experiments. Immunostaining was performed by incubating the cells with a primary antibody to perilipin-2 (guinea pig polyclonal, 1:200) ( Fitzgerald Ind. 20R-AP002) or cPLA2-α (mouse monoclonal, 1:100) (Santa Cruz, sc-454, 4-4B-3C). Primary antibodies were targeted with anti-guinea pig (goat) (Invitrogen, A1076) or anti-mouse (goat) (Invitrogen, A1005) Alexa Fluor 594-conjugated secondary antibodies. Coverslips were mounted on glass microscope slides (Fisher Scientific, 12-550-14) using glycerol-free mounting media Vectashield H-1000 (Vector).

2.10. MTT assay for cell viability

The MTT assay was performed as described previously [9]. N9 microgla were seeded in 24-well plates (5 × 10⁴ cells/well, area per well = 2 cm²) (Sarstedt, 83.1836), cultured overnight and then treated with the inhibitors, oleic acid and LPS for 12 h as described in the figure legends. Mitochondrial metabolic activity in viable cells was determined by conversion of MTT (thiazolyl blue tetrazolium bromide) (M2128, Sigma) to formazan. The absorbance from dissolved formazan in DMSO was measured spectrophotometrically at 594 nm.

2.11. Statistical analysis

Statistical analysis was performed using Systat (version 13). Comparisons between multiple groups were done by ANOVA, followed by post hoc tests such as Tukey’s or Dunnett’s. T-tests were used when comparing only two groups. All data are presented as group means ± SEM. The Fischer exact test (two-tail) was used to test for differences in proportions of small, medium and large LDs between their different populations in 2 × 2 tables. In all statistical tests, values of p < 0.05 were considered significant.

3. Results

3.1. LPS induces LD accumulation, alters LD size distribution and increases triglyceride content

Binding of LPS to TLR4 leads to the activation of TLR4 signal transduction pathways known to induce NO synthase expression. Therefore, we measured the concentration of NO in the culture media following LPS (10 μg/ml) treatment for 6 and 24 h. LPS treatment resulted in a dramatic increase in NO release (55.5 ± 1.8 μM) when compared with untreated cells (0.4 ± 0.6 μM) (p < 0.005) (Supplemental Fig. 1). We sought to assess LD dynamics during microglial activation by examining changes in LD numbers and volumes. Using confocal microscopy, we monitored the dynamics of microglial LDs, which were visualized with the neutral lipid-selective fluorescent dye BODIPY 493/503. Cells treated with LPS (10 μg/ml) for 12 h displayed significantly elevated number of LDs, as compared to non-stimulated microglial cells (Fig. 1A). OA, a monounsaturated long chain fatty acid, is known to be a potent inducer of LDs [7] and was therefore used as a positive control. We observed a marked accumulation of LDs in cells supplemented with OA (50 μM) for 12 h (Fig. 1A). In contrast to LPS, however, OA did not stimulate NO release from microgla (Supplemental Fig. 1). The number of LDs per cell (#LD/cell) was determined at each of the different timepoints (3, 6, 9, 12 and 24 h) following LPS or OA treatment. LPS caused a time-dependent increase in #LD/cell, with a maximum number observed
by 12 h of LPS treatment (8.7 ± 0.7 vs. 4.6 ± 0.6 in untreated cells) (p < 0.05) (Fig. 1B). OA treatment rapidly increased LD content in microglial cells, causing a ~16-fold increase in #LD/cell (113 ± 13 in treated vs. 7 ± 2 in untreated) after 3 h (p < 0.005) (Supplemental Fig. 2A). Typically, LDs are heterogeneous with respect to their sizes, as well as their lipid [34,35] and protein content [36]. In N9 microglia, LDs with a diameter ranging from ~250 nm to 2 μm or even greater can be detected by confocal microscopy (our unpublished observations). In addition to an induction of LD number by inflammatory stimuli, an increase in LD size has also been seen in inflammatory...
macrophages [37]. Therefore, we assessed the effect of LPS on the size distribution of LDs in microglial cells. After 12 h of LPS treatment, we observed a significant reduction (−19.8%, p<0.005) in the relative abundance of small LDs, accompanied by an increase in the relative abundance of medium LDs (+18.6%, p<0.005) and large LDs (+1.2%, not significant) (Fig. 1C). OA exerted a pronounced effect on LD size distributions (Supplemental Fig. 2B). A reduced relative abundance of small LDs (−26%, p<0.005) and concomitant increase of medium and large LDs (24%, p<0.005 and 2%, p<0.005, respectively) were seen within three hours (Supplemental Fig. 2B). These findings imply that LPS alters LD size distribution in microglia, although to a much lesser extent than OA. Our data show that LPS-activated microglia have a higher LD content than untreated microglial cells and that LPS and OA greatly differ in the extent to which they induce LD accumulation and alter LD sizes.

To further demonstrate that LPS leads to LD accumulation, we performed mass spectrometry-based lipidomic analysis to determine changes in the levels of triglycerides (TG), the major neutral lipids found in LDs. Following their extraction from microglia treated with LPS for 9 h, TG levels were measured by quantitative electrospray ionization mass spectrometry (ESI-MS). Cells treated with LPS displayed a significant increase in total cellular TG levels (Fig. 1D) and in TG species 52:2 and 54:3, thereby supporting the observed increase in LD content in activated microglia. TG synthesis requires incorporation of long-chain fatty acyl-CoAs into glycerol-3-phosphate, monoacylglycerol and diacylglycerol [38]. Treatment with triacsin C abolished the increase in LDs induced by LPS, suggesting that de novo synthesis of TGs was required under this condition (Fig. 1E and Supplemental Fig. 1B).

3.2. LPS-induces activation of JNK and p38 MAPK and stimulates perilipin-2 expression

JNK and p38 MAPKs are key players in LPS-induced inflammatory response of microglia [40]. JNK activation leads to transcriptional activation of AP-1, a heterodimeric transcriptional complex [26]. It has been reported that LPS-induced perilipin-2 expression is in part mediated by an increased binding activity of AP-1 to the Ets/AP-1 element on the perilipin-2 gene promoter [27]. We first explored the effect of LPS on p38 and JNK by determining the extent of their phosphorylation by Western blot analysis. LPS induced a significant increase in p38 phosphorylation after 15 min of treatment (p<0.01) (Fig. 2A & B). LPS also caused a rapid (15 min), transient and robust increase in JNK phosphorylation (p<0.005) (Fig. 2C & D). In contrast, neither p38 nor JNK were activated following OA treatment at any timepoint between 0 and 120 min (Supplemental Fig. 2C).

Perilipin-2 has been reported to stimulate neutral lipid accumulation and LD formation in macrophages and fibroblasts [19,41]. In macrophages, LPS increases perilipin-2 expression leading to LD accumulation [27,28]. To date, the role of perilipin-2 has not been investigated in neural cells. We hypothesized that activation with LPS will increase perilipin-2 protein levels in microglia. Following LPS stimulation, perilipin-2 levels increased in a time-dependent manner with a peak at 9 h after LPS addition corresponding to a ~3-fold increase (p<0.05) over the control (Fig. 3A & B). Immunostaining experiments of perilipin-2 indicated that the protein colocalizes with LDs in LPS-treated cells (Fig. 3C). In the experiments with our positive control, we observed a significant increase (>3-fold, p<0.05) in perilipin-2 expression after 3 h of OA treatment (Supplemental Fig. 3A & B).
Moreover, perilipin-2 extensively colocalized with LDs (Supplementary Fig. 3C). Altogether, the above data imply that LPS rapidly activates MAPK pathways and leads to an increase in perilipin-2 expression in microglia.

3.3. LPS-induced LD formation is blocked by inhibitors of p38 and PI3K, but not by an inhibitor of JNK

To investigate whether MAPK activation regulates LD formation, LPS-stimulated microglia were treated with selective inhibitors of JNK (SP600125) and p38 (SB203580). We found that in the presence of LPS, SP600125 (10 μM) further increased the LD number/cell (Fig. 4A & B). In contrast, SB203580 (10 μM) reduced the LD number/cell (p < 0.005) (Fig. 4A & B). However, SB203580 also reduced the LD number/cell under basal conditions (p < 0.005). We also examined whether inhibition of p38 downregulates perilipin-2 expression in LPS-stimulated microglia. Indeed, SB203580 treatment, though not SP600125 treatment, significantly decreased perilipin-2 expression in LPS-treated microglia (Fig. 4C). It has been demonstrated that SB203580, when used at concentrations above 2–3 μM, can block the phosphorylation and activation of Akt/protein kinase B (PKB) by inhibiting 3-phosphoinositide-dependent protein kinase 1 (PDK1) [42]. Akt/PKB, a serine-threonine kinase is activated by growth factors and plays a central role in cell survival, growth and proliferation. Interestingly, Akt/PKB was also shown to promote...
accumulation of LDs in Drosophila nurse cells [43]. To examine whether Akt/PKB is a regulator of LD formation, we treated microglia with an inhibitor (LY294002) of class I phosphatidylinositol 3-kinase (PI3K), an upstream activator of Akt/PKB. LPS-induced LD accumulation in microglia was blunted by LY294002 treatment (p < 0.005) (Fig. 4A & B). The inhibitor also reduced perilipin-2 expression (Fig. 4C). Together, these data implicate the p38 MAPK and PI3K/Akt pathways in the regulation of LD formation in LPS-treated microglial cells.
3.4. p38 and PI3K inhibitors do not block OA-induced LD formation, but decrease the size of LDs

Roles for p38 MAPK and PI3K activation in OA-induced LD formation have been previously reported in epithelial cells [15]. To examine whether p38 and PI3K regulate OA-induced LDs in microglia, we tested their effect on LD formation by confocal microscopy. SB203580 or LY294002 did not block the induction of LDs by OA (Supplemental Fig. 5 A&B), but they did markedly decrease the average size (volume) of LDs (p < 0.01) (Supplemental Fig. 5C).

3.5. In microglia, cytosolic phospholipase A2 (cPLA2) colocalizes with LPS-induced LDs, but not with OA-induced LDs

LDs in leukocytes were previously shown to contain significant amounts of esterified arachidonate in their triglyceride and phospholipid pools [13]. Different eicosanoid-synthesizing enzymes, including the key enzyme for the release of arachidonic acid, cPLA2-α, compartmentalize at LDs in human monocytes (U937) and rat intestinal (IEC-6) epithelial cells [13,15]. We asked whether or not the newly formed LDs in LPS-treated microglia play a function in eicosanoid synthesis. To address this question, we examined by confocal microscopy the colocalization of cPLA2-α with LDs in LPS-treated microglia. Colocalization of cPLA2-α with LDs could not be assessed in untreated cells, because LDs were almost entirely absent (Fig. 5A). LPS induced the formation of many LDs which colocalized with cPLA2-α (Fig. 5A, bottom row). In contrast, OA-induced LDs did not colocalize with cPLA2-α. Treatment with LPS or OA did not alter the protein levels of cPLA2-α (Fig. 5B).

4. Discussion

In this report we show that LPS-induced TLR4 activation in microglia is accompanied by marked changes in intracellular lipid droplet (LD) status as manifested by an increase in the number and volume of LDs in the cells. LPS also increased the expression of perilipin-2, a major LD surface-associated protein. We attribute this effect of LPS on LDs to the activation of p38 MAPK, since inhibition of p38 suppressed LPS-induced perilipin-2 expression and LD formation. Taken together, our results suggest that LDs are actively involved in LPS-induced inflammatory response in microglia.

We first demonstrated that LPS-mediated TLR4 activation in microglia leads to LD accumulation. In vivo studies in mice have demonstrated that LD number in leukocytes is increased following LPS administration [12]. Because of their implication in the innate immune response, LDs were described as “inflammatory organelles” that can serve as key markers of cell activation [44] We showed that in LPS-challenged microglia, the increase in the LD number was significant. However, temporal analysis of LDs over a 24 h period following LPS stimulation demonstrated that the initial increase in LD number does not persist; after reaching a peak following 12 h of LPS treatment, the number of LDs decreased. This decrease could be explained by increased fusion between LDs, leading to larger, but fewer LDs in the cells. LD fusion is an inducible process [45,46]. In fact, LPS did cause marked changes in the LD size distribution pattern in microglia, shifting the balance towards larger LDs and reducing the abundance of small-sized LDs. We speculate that the enlargement of LDs in LPS-stimulated microglia was caused, at least in part, by activated homotypic fusion of their smaller forms. Treatment with LPS resulted in a significant increase in cellular TG levels in microglia. The effect of LPS on lipid synthesis in macrophages has been previously examined [47,48]. It was demonstrated that macrophages (RAW 264.7) treated with LPS accumulate TG, but not cholesterol esters (CE) [48]. An in vivo study showed that LPS increased both TG and CE levels in peritoneal macrophages [47]. In microglia, LD accumulation triggered by LPS required TG biosynthesis, since triacsin C, an inhibitor of long-chain acyl-CoA synthetase (ACSL) activity, blocked the induction of LDs by LPS. Whether CE levels increase concurrently with TG levels in LPS-treated microglia should also be determined in future studies.

In parallel with LPS, we supplemented microglia with OA, a dietary monounsaturated fatty acid. As expected, OA strongly induced LD formation and caused marked changes in the pattern of LD size distribution. Upon entering the cell, unsaturated free fatty acids (FFAs) are rapidly activated by becoming converted to their CoA esters. TGs consist of three fatty acid chains attached to a glycerol backbone by ester bonds. In the final reaction of TG synthesis, a fatty acyl-CoA and diacylglycerol are covalently attached in an esterification reaction catalyzed by the enzyme acyl-CoA:diacylglycerol acyltransferase (DGAT) [49]. The esterification-driven conversion of FFAs into stored TGs is considered a protective mechanism against FFA-induced lipotoxicity [50]. In the present study, OA treatment in microglia did not induce cytotoxicity and displayed no activating effect on JNK and p38 MAPK.

We further demonstrated that LPS treatment increases perilipin-2 protein expression. The increase in perilipin-2 expression took place before the increase in the number of LDs, suggesting that new perilipin-2 protein synthesis was required for LPS-induced LD formation. In fact, using actinomycin D and cycloheximide, Gu et al. demonstrated that in RAW 264.7 macrophages LPS-induced perilipin-2 expression was stimulated at the transcriptional level and was mediated by new protein synthesis [27]. Post-translational mechanisms were shown to regulate perilipin-2 via the ubiquitin/proteasome proteolytic pathway [21]. Increased cellular neutral lipids (e.g. triglyceride) stabilize perilipin-2 and prevent its degradation by the proteasome [51]. Therefore, similar mechanisms could contribute to increased perilipin-2 levels in microglia accumulating TGs.

We observed a robust induction of perilipin-2 in OA-supplemented microglia. Fatty acids can bind peroxisome proliferator activated receptors (PPAR) α- and γ and thereby regulate gene expression [52]. A PPAR response element (PPRE) is located in the promoter region of perilipin-2 [53] and regulates perilipin-2 expression in OA-treated cells [54]. OA was also shown to affect the post-translational regulation of perilipin-2 (ADRP). Indeed, OA treatment reduced levels of polyubiquitinated perilipin-2 and prevented its proteolytic degradation [21].

JNK and p38 MAPKs play an important role in the pro-inflammatory actions of microglia and macrophages [55,56]. Their activity is highly regulated by TLR4-generated signals. TLR4 agonists, such as LPS, induce homodimerization of the TLR4/MD-2 complex and trigger a downstream signaling cascade involving IRAK and TAK1. This leads to activation of MAPK kinases (MKK) 3, 4, 6 and 7 [26]. MKK3/6 mainly phosphorylate p38, whereas MKK 4/7 phosphorylate JNK. Phosphorylation of c-Jun and ATF2 by JNK and p38 increase the transcriptional activity of AP-1, leading to expression of inflammatory cytokines [26]. The effects of LPS on microglia have been previously investigated [57,58]. In BV2 microglia, LPS-induced activation involves iNOS expression, Nf-κB activation, p38 phosphorylation, reactive oxygen species production and cyclooxygenase -- 2 expression [57]. Interestingly, OA showed an anti-inflammatory effect by reducing the proinflammatory effects of LPS. In agreement with these studies, we showed that in N9 microglia LPS caused rapid and transient stimulation of JNK and p38 MAPK and increased NO production. OA treatment had virtually no stimulating effect on JNK, p38 and NO release. Taken together, these findings reveal differential effects of OA and LPS on the TLR4-initiated signal transduction pathway.

Fig. 5. Cytosolic phospholipase A2-α (cPLA2-α) colocalizes with LDs induced by LPS, but not with LDs induced by OA treatment. Microglia were treated with LPS (10 μg/mL) or OA (50 μM) for 9 h. (A) Confocal images show LDs labeled with HCS LipidTox (pseudocolored green) and immunolabeled cPLA2-α (red). Note that cPLA2-α colocalized with LDs (merged images; bottom row, middle panel). Images are representative of two independent experiments. Scale bar = 5 μm. (B) Western blot analysis of cPLA2-α in cells treated with LPS or OA. Actin was used as a loading control.
We demonstrated that the inhibition of p38 MAPK or PI3K, but not the inhibition of JNK, downregulates LPS-induced perilipin-2 expression and LD accumulation. SP600125 inhibits JNK 1/2 with high specificity [59]. SP600125 treatment further increased LD formation in LPS-stimulated microglia, contrary to our expectations. The growing body of evidence implies the existence of a crosstalk between JNK and other kinases. Activation of the PI3K/Akt pathway and ERK1/2 following inhibition of JNK with SP600125 have been reported in macrophages and neurons [40,60]. Of note, ERK 1/2 and Akt/PI3K signaling pathways were implicated in regulating LD formation in macrophages [61]. It is conceivable, therefore, that under LPS treatment, pharmacological inhibition of JNK causes a compensatory activation of either ERK1/2 or Akt/PI3K pathway, leading to increased LD formation. The inhibitor of 38 MAPK, SB203580, abolished the increase in perilipin-2 expression and LD accumulation caused by LPS treatment. It was previously shown that SB203580 inhibits LPS-induced activation of p38 MAPK and transcription factor AP-1 in macrophages [62]. Considering that LPS can enhance perilipin-2 promoter activity by activating AP-1, the suppression of perilipin-2 by SB203580 in LPS-treated microglia could have been mediated by the inhibition of AP-1. In the absence of LPS, SB203580 also reduced the number of LDs. This could have been caused by the off-target inhibitory effect of SB203580 on the Akt/PKB signaling pathway, as previously reported in experiments applying the inhibitor at concentrations above 2–3 μM [42]. In sum, our study revealed that both LPS and OA can stimulate LD formation and perilipin-2 expression in microglia, but with different dynamics and to a remarkably different extent. OA is a much more potent inducer of LD formation and perilipin-2 expression, as compared to LPS. Our results reveal at least two distinct signaling pathways involved in LD formation in microglia. Whereas OA induces LD formation in a MAPK independent manner, LPS induces LD accumulation by strongly activating p38 (Fig. 6). The presence of colocalization between cPLA-α and LPS-induced LDs indicates a potential role for these organelles in the regulation of eicosanoid synthesis in activated microglia.

We suggest that LDs induced by LPS play an important regulatory role in the microglial inflammatory response. Altogether, our findings imply that in the central nervous system, specific changes in the biogenesis of LDs and their proteins may contribute to regulation of pathologies associated with inflammation.
